Abstract

Four atmospheric pressure ozone oxidation methods were used to produce ultra-thin layers of aluminum oxide for organic thin-film transistors. They are UV/ozone oxidation in ambient (UV-AA) and dry (UV-DA) air, UV/ozone oxidation combined with high-voltage discharge-generated ozone in dry air (UV+O3-DA), and discharge-generated ozone in dry air (O3-DA). The lack of the high-energy UV photons during the O3-DA oxidation led to low relative permittivity and high leakage current density of the AlOx layer that rendered this method unsuitable for transistor dielectrics. Although this oxidation method led to the incorporation of oxygen into the film, the FTIR confirmed an increased concentration of the subsurface oxygen while the XPS showed the highest portion of the unoxidized Al among all four methods. The remaining three oxidation methods produced AlOx films with thicknesses in excess of 7 nm (2-h oxidation time), relative permittivity between 6.61 and 7.25, and leakage current density of (1–7) × 10–7 A/cm2 at 2 MV/cm, and were successfully implemented into organic thin-film transistors based on pentacene and DNTT. The presence of –OH groups in all oxides is below the detection limit, while some carbon impurities appear to be incorporated.

Organic thin-film transistors

1 Introduction

The ultra-thin and high-K dielectrics lead to field-effect transistors with low operating voltages. However, to achieve good transistor operation such dielectrics must also exhibit very low leakage current. HfLaO (k ~ 15.3) [1,2], Ba1.2Ti0.8O3 (k ~ 15.57) [3], SrTiO3 (k ~ 12.1) [4], and high-K polymers dielectrics (k ~ 12.6) [5] have been explored for low-voltage organic thin-film transistors (OTFTs). OTFTs with medium-K gate dielectrics such as aluminum oxide (k ~ 6.2) [6] have achieved low operating voltages through reduction in their thickness [7]. The aluminum oxide is often further functionalized by organic monolayers to provide reduction in the leakage current and the surface energy [8].

Standard deposition methods for aluminum oxide include sputtering and atomic layer deposition. However, ultra-thin layers of aluminum oxide can also be prepared by oxidation of aluminum deposited in high-vacuum by thermal vaporization [9,10], ozone oxidation, or anodic oxidation [12]. The reactive atomic oxygen required for the oxidation of aluminum can also be produced by dissociation of ozone [13] and the reaction can be performed at atmospheric pressure. UV/ozone oxidation was previously used in the preparation of high-K gate dielectrics for CMOS. Some examples include hafnium silicate [14], zirconia [15] and hafnium-aluminum oxynitride [13].

The oxidation of aluminum was performed in UV/ozone cleaner (H2O2:H2O:O3:H2:2% N2O), a high-pressure mercury lamp
emits UV light at 184.9 and 253.7 nm [16]. The higher energy photons are absorbed by the molecular oxygen, leading to ozone formation. The lower energy photons do not generate ozone. They illuminate the oxidizing surface, dissociate ozone, and assist in the removal of organic contaminants [17,18]. High-voltage discharge can also generate ozone [13]. Common commercial applications include water treatment and sanitation. Contrary to mercury lamps, the discharge produces ozone without the coexistence of high energy photons and the efficiency of the ozone generation depends on the relative humidity of the air. The results of this paper show for the first time that the ozone production method can have a profound effect on the properties of the produced AlOx.

2. Experimental procedures

Four methods were used to oxidize the aluminum lines deposited on glass substrates. Samples for spectroscopic ellipsometry, X-ray photoelectron spectroscopy (XPS) and Fourier Transform Infrared Spectroscopy (FTIR) were oxidized according to the conditions shown in Table 1 and the oxidation time was 2 h. The fifth sample was left to oxidize in dark ambient conditions to form a native oxide (Native AA). Finally, the UV-AA oxidation ranging from 5 min to 6 h was used to produce 6 samples. This allowed studying the thickness of the UV-AA AlOx as a function of oxidation time.

Metal–insulator–metal (MIM) structures and organic thin-film transistors (OTFTs) were fabricated to study the effect of AlOx oxidation process. Al/AlOx/DNTT/Au and Al/AlOx/C8PA/pentacene/Au transistors were fabricated for four AlOx oxidation procedures listed in Table 1 (DNTT stands for dinaphtho[2,3-b:2',3'-f]thieno[3,2-b:2',3'-f]thiophene and C8PA for n-octylphosphonic acid monolayer). The fabricated transistors have channel lengths of 30, 50, 70, and 90 μm and a channel width of 1000 μm. The corresponding MIM structures were fabricated alongside. Each sample contained 12 transistors and 4 MIM structures.

MIM structures were fabricated as follows. 30-nm-thick aluminum lines were deposited on glass substrate. One end of the lines was capped by gold layer to prevent their oxidation. AlOx was prepared by using the four methods described above. In some samples, the AlOx was functionalized with vapor-assembled monolayer of n-octylphosphonic acid (C8PA) using the procedure described in [19]. The presence of monolayer on top of aluminum oxide reduces the leakage current and changes the hydrophilic surface into hydrophobic [8]. The vacuum vapor growth of C8PA monolayer was optimized with respect to the post-deposition annealing time [19,20], deposition temperature [21], and deposition rate [22]. All capacitors were completed by evaporating a 50-nm-thick gold layer [19]. The area of the capacitors was about 0.2 mm².

Bottom-gate, top-contact organic thin-film transistors (OTFTs) based on thermally evaporated DNTT (Sigma–Aldrich) or pentacene (Tokyo Chemical Industry) followed the same fabrication procedure. A 15-nm-thick DNTT was deposited directly on AlOx, while a 50-nm-thick pentacene layer was deposited on AlOx functionalized with C8PA. Both transistor sets were completed by evaporating gold source and drain contacts. The cross-sections of pentacene and DNTT OTFTs are shown in Fig. 1. All fabrication steps were performed by using shadow masks. All thermal evaporation steps were conducted in Minispectros (Kurt J. Lesker) high vacuum system (~10⁻⁷ mbar) enclosed in a N₂-filled glove box.

The capacitor and transistor measurements were performed with Agilent B1500A semiconductor device analyzer under ambient environmental conditions. All fabricated devices were kept in oxygen and moisture-free environment until their measurement and they shared the same history. The gate dielectric capacitance of MIM structures was measured between 1 kHz and 1 MHz. The MIM current density was measured as a function of applied electric field. The transfer and output characteristics of the OTFTs were measured in a sweep mode. All fabricated MIM structures and transistors were measured for each AlOx oxidation process. Mean values and standard deviations were calculated for all parameters.

The spectroscopic ellipsometry was performed with a J.A. Woollam M2000V in ambient air. Glass/Al/AlOx samples were measured and fitted with a three-layer model using a B-spline fit. FTIR was measured with Ge detector in reflection mode with Nicolet 380 spectrometer in ambient air. The beam diameter was ~1.5 mm. PeakFit analysis provided the location of the peaks, their intensity, full width at half maximum (FWHM), and integral area. Polycrystalline white corundum was also measured for comparison. X-ray photoelectron spectroscopy was carried out in a SAGE 100 system (Specs GmbH) using a non-monochromatic MgKα source, with a beam diameter of 7 mm, operated at 10 kV (150 W). The base pressure during the analysis was around 2 × 10⁻⁷ mbar. Spectra were recorded at a take-off angle of 90 degrees with a pass energy of the hemispheric analyzer of 50 eV for survey scans and 15 eV energy for high-resolution scans.
for detailed scans. Results were analyzed in commercial casaXPS software and composition was determined using peak fitting with a standard Shirley background. AlOx/Al layers prepared in 4 different ways were examined. In addition, Al layer with native oxide and bulk sapphire material were measured for comparison. The sapphire was cleaned in situ with Ar plasma prior to the measurement while the AlOx layers were not.

3. Results

3.1. Material characterization

Fig. 2a shows the AlOx thickness obtained from the ellipsometry measurements. The UV/ozone oxidation in ambient air (UV-AA) resulted in AlOx thickness of 7.06 ± 0.07 nm. The removal of the moisture from ambient air (UV-DA) led to a slightly thicker AlOx layer of 7.15 ± 0.08 nm. The combination of mercury lamp and discharge-generated ozone (UV+O3-DA) led to the highest thickness of 7.19 ± 0.09 nm. However, these three values are the same within the standard deviation. Finally, the discharge-generated ozone (O3-D) produced AlOx of 6.85 ± 0.11 nm.

Fig. 2b depicts the measured capacitance of the AlOx and AlOx/C8Pt PA MIM structures with AlOx prepared using four different procedures. Going from UV-AA, to UV-DA and UV+O3-DA, the AlOx capacitance is gradually decreasing from ~0.90 to ~0.80 μF/cm2. However, the capacitance of the O3-DA AlOx layer is substantially lower, reaching only 0.46 μF/cm2. AlOx/C8PA bi-layers prepared by discharge-generated ozone (O3-DA) exhibit the lowest capacitance of 0.36 μF/cm2, while the remaining procedures led to a value of ~0.60 μF/cm2. Finally, Fig. 2c shows the relative permittivity of AlOx calculated from the known capacitance and thickness values. The relative permittivity decreased from 7.25 to 7.13 when the moisture was removed from the air. The addition of the discharge-generated ozone led to a further decrease in εr. However, the removal of the UV photons from the oxidation process resulted in a substantial reduction in εr to 3.58. Finally, the inset in Fig. 2a shows that the thickness of AlOx prepared by UV/ozone oxidation in ambient air (UV-AA) follows approximately a square root dependence on the oxidation time with power exponent of 0.52.

Fig. 3 shows the leakage current density of AlOx and AlOx/C8PA MIM structures plotted as a function of applied electric field for different AlOx preparation methods. The reduction in the air humidity from ~45% to ~0.1% led to a slight reduction in the AlOx leakage current density when the UV lamp was used to produce the ozone (UV-AA versus UV-DA). Combination of the UV lamp and discharge-generated ozone (UV+O3-DA) led to the lowest leakage current. If the UV lamp is not turned on and the ozone is produced via discharge (O3-DA), the leakage current increases by several orders of magnitude. Qualitatively, the leakage current density is decreasing with increasing AlOx thickness. However, the leakage current of UV-AA AlOx is ~3 orders of magnitude lower than that of O3-DA AlOx, even though the difference in their thickness is only 3%.

When AlOx is functionalized with C8PA, the leakage current density is suppressed. With the exception of the discharge-generated ozone the leakage current density is ~2–3 × 10−7 A/cm2 at the field of ~3 MV/cm. A visibly higher leakage current is observed for AlOx/C8PA bi-layers with AlOx produced with discharge-generated ozone (O3-DA). Clearly, the presence of UV photons during the oxidation process is important for the leakage current reduction.

Fig. 4 shows XPS spectra for AlOx layers prepared by different oxidation procedures. The spectrum of native oxide and bulk sapphire are also shown for comparison. Fig. 4b shows the section of XPS spectra corresponding to Al 2s and Al 2p peaks. With the exception of sapphire, all other Al 2s and Al 2p peaks exhibit a low energy ‘shoulder’, indicating presence of non-oxidized Al atoms.

Fig. 5a depicts the Al/O ratio obtained for AlOx layers shown in Fig. 4. The ratio was calculated using the integrated intensities of the Al 2p and O 1s peaks and atomic sensitivity factors for Al and O. The ratio varied between ~1.1 and ~1.2 for various oxidation methods. The ratio measured for sapphire was 0.68, a value close to 3.
to the stoichiometric composition of Al₂O₃. UV-AA and O₃-DA AlO₅ have similar Al/O ratio of ~1.15. Other than the native AlO₅, UV-DA AlO₅ exhibits the highest Al/O ratio of ~1.20, while UV+O₃-DA AlO₅ has Al/O ratio of ~1.10. (These high Al/O values are reduced for AlO₅ layers with thickness in excess of 8 nm, confirming that the electron escape depth is approximately 8 nm.) Fig. 5b depicts the ratio between the area of the lower-energy shoulder and the main peak for both Al 2s and Al 2p counts shown in Fig. 4b. The ratio for sapphire is zero, as all Al atoms are bonded to O. Since the low-energy peaks may be associated with the underlying Al, the smallest and largest ratio would be expected for UV+O₃-DA AlO₅ (largest thickness of 7.19 nm) and the native oxide (1.67 nm), respectively. This is indeed observed experimentally. UV-AA AlO₅ is only 3% thicker than O₃-DA oxide. However, the discharge-generated ozone without the presence of UV photons resulted in a larger portion of unoxidized Al atoms.

Fig. 6a shows a section of the FTIR absorbance in the region between 700 and ~1000 cm⁻¹ that captures the stretching Al–O vibrations (bending vibrations are located below 500 cm⁻¹ [23]). Polycrystalline white corundum shows a broad peak that reaches maximum at 730 cm⁻¹ and a weaker absorption centered near 793 cm⁻¹. In addition, minute absorption is also located near 770 and 899 cm⁻¹. The Al–O absorbance of AlO₅ layers prepared using ozone oxidation techniques is shifted to higher wavenumbers. A small peak is observed at 731 cm⁻¹ coinciding with the absorbance in corundum. The large broad bands are a superposition of three main absorbances located at ~850, ~900, and ~950 cm⁻¹. However, their amplitude and relative contribution to the absorption band are changing with the oxidation method. The absorbance reaches maximum at ~930 cm⁻¹ for UV-AA, UV-DA and UV+O₃-DA oxides. On the contrary, the absorbance peaks are similar for O₃-DA and native oxides. They reach maximum at lower wavenumbers due to the highest amplitude at 850 cm⁻¹. The shape of the absorbance is somewhat correlated with the relative permittivity of Al₂O₃: higher εᵣ results in the higher contribution of the high-wavenumber absorbance.

The assignment of the absorbance peaks of ozone oxidized layers is difficult. It is well known that compounds which contain AlO₄-tetrahedra in their structure exhibit an absorption band at higher wavenumbers than materials consisting of AlO₆-octahedra. In addition, the disorder in amorphous films leads to a distribution in the oscillator strengths and frequencies of Al–O stretching modes, resulting in broad absorbance peaks. The Al–O bond length also affects the position of the Al–O band; the absorbance at higher wavenumber results from shorter Al–O bonds [24]. For example, the subsurface oxygen exhibits a stretching mode between 820 and 875 cm⁻¹ [25]. The Al–O–H deformation mode is also present near 850 cm⁻¹. This mode was observed at 840 cm⁻¹ for the condensation reaction of octadecylphosphonic acid onto aluminum oxide/hydroxide surface [26] and measured near 840–847 cm⁻¹ in kaolinites [27]. However, the associated Al–O–H stretching modes are expected between 3200 and 3700 cm⁻¹ [28] where they overlap with the H–O–H stretching mode of water. The AlO₅ layers of Fig. 6 do not show measurable absorbance above 3000 cm⁻¹. Consequently, the absorbance near 850 cm⁻¹ is associated with the presence of subsurface oxygen instead of –OH groups, indicating that the UV light promotes oxygen diffusion from the surface inward.

Not counting the native AlO₅, the largest integral intensity is measured for UV-AA oxide and the lowest for O₃-DA AlO₅ even though their thicknesses are comparable (see Fig. 2a). The use of dry air (UV-DA, UV+O₃-DA and O₃-DA) produced lower integral absorbance than the ambient air. Overall, the integral absorbance is not correlated with the AlO₅ thickness. Since the reflectivity of Al in the region between 2.5 and 25 µm is >98%, the contribution from the underlying Al and glass to the IR absorbance can be neglected.

Fig. 6b shows the region of symmetric and antisymmetric stretching vibrations of methyl and methylene groups. Fig. 4a shows the presence of C 1s peaks for all AlO₅ layers regardless of their preparation and the FTIR measurements suggest that some of this carbon is incorporated in the AlO₅ layers. UV-AA and O₃-DA AlO₅ exhibit the highest peak amplitudes, followed by slightly lower absorbance from UV+O₃-DA, and the lowest absorbance from UV-DA and native AlO₅. The insignificant absorbance measured for corundum is ascribed to ambient methane. Qualitatively similar behavior with respect to peak amplitudes is observed in the region from ~1300 to ~1500 cm⁻¹ (rocking, wagging, and bending modes of –CH₂ and –CH₃).

Fig. 5. Al/O ratio (a) and Al 2s and Al 2p peak-ratios (b) for AlO₅ layers of Fig. 4.
3.2. OTFT properties

In this section, OTFT properties are presented for all oxidation methods other than O$_3$-DA due to the excessive leakage current density produced with this method. The transfer and output characteristics of Al/AlO$_x$/C$_8$PA/pentacene/Au transistor with $L = 24 \mu$m and $W = 1000 \mu$m are shown in Fig. 7. The threshold voltage and field-effect mobility of Al/AlO$_x$/DNTT/Au transistors are shown in Fig. 8a and b. Although the functionalization of AlO$_x$ with phosphonic acid is preferred for DNTT transistors, the transistor parameters are affected by the quality of AlO$_x$ and its interface with DNTT and thus provide valuable information [29]. The threshold voltage is $V_t \approx 1.15$ V for the UV-AA and UV-DA oxidations and $V_t \approx 1.25$ V for UV+O$_3$-DA AlO$_x$. The field-effect mobility is $0.0014$ cm$^2$/Vs for UV-AA, $0.017$ cm$^2$/Vs for UV-DA and $0.0007$ cm$^2$/Vs for UV+O$_3$-DA oxidations. The threshold voltage and field-effect mobility of Al/AlO$_x$/C$_8$PA/pentacene/Au transistors are shown in Fig. 8c and d. The threshold voltage is $V_t \approx 1.5$ V for the UV-DA and UV+O$_3$-DA oxidations and $V_t \approx 1.3$ V for UV-AA AlO$_x$. The field-effect mobility is $0.055$ cm$^2$/Vs for UV-AA and UV+O$_3$-DA oxidations and $0.045$ cm$^2$/Vs for OTFTs with UV-DA AlO$_x$.

4. Discussion

UV-AA and UV-DA oxides are both prepared under UV lamp using different level of moisture in the ambient air. The reduction from $45$ to $<0.1$ RH% led to an increase in the oxide thickness from $7.06$ to $\sim 7.15$ nm, a decrease in $\varepsilon_r$ from $7.25$ to $7.13$, a factor of two reduction in the leakage current density, a slight increase in the Al/O ratio and the fraction of unoxidized Al, and reduction in Al–O absorbance and absorbance associated with C impurities. These results confirm that dry air oxidation results in lower oxygen and carbon content in the formed AlO$_x$ layer.

At the same time, the threshold voltage of the DNTT transistors was similar, while the $|V_t|$ of pentacene transistors was increased by $\sim 0.2$ V. The field-effect mobility increased by an order of magnitude for DNTT transistors and reduced by $\sim 20\%$ for pentacene transistors. Since the growth of both pentacene [30] and DNTT [31] depends on the surface energy of the underlying surface, the change in the field-effect mobility of DNTT OTFTs suggests change in the AlO$_x$ surface chemistry between ambient and dry air oxidations. After the AlO$_x$ surface is modified with C$_8$PA monolayer, C$_8$PA...
surface properties control the pentacene growth, resulting in similar OTFT field-effect mobilities.

Comparison of UV-DA and UV+O3-DA oxides reveals the effect of the added ozone produced via high-voltage discharge. The addition of the discharge-generated ozone leads to a marginal increase in the oxide thickness, slight decrease in its $\varepsilon_r$, a factor of two reduction in the leakage current density, decreased Al/O ratio and the fraction of unoxidized Al, increased Al–O absorbance and similar absorbance associated with C impurities. An increase in $|V_i|$ of DNTT transistors by ~0.1 V and a slight reduction in $|V_i|$ for pentacene transistors were observed. The field-effect mobility was reduced by a factor of ~25 for DNTT transistors and increased by ~20% for pentacene transistors. Overall, the addition of ozone produced via high-voltage discharge did not improve the properties of AlO$_x$ layer, even though there was a slight improvement in the $\mu_{eff}$ for both DNTT and pentacene transistors. Finally, UV-AA films with similar integral area with Al networks due to presence of carbon is similar in both oxides. One can infer from this that while both oxides contain comparable amount of oxygen, the presence of high-energy photons during UV-DA oxidation facilitates the diffusion of the O atoms and their insertion into the Al network, resulting in stronger Al–O vibration peak, factor of two higher $\varepsilon_r$, and a factor of ~500 smaller leakage current density.

The threshold voltage is also affected by the oxidation of aluminum. The lowest threshold voltage was achieved for UV-AA oxidized AlO$_x$ for both DNTT and pentacene transistors. Finally, all OTFTs exhibit field-effect mobility lower than that reported by others [29,32,33] and further optimization is required to increase the mobility of DNTT OTFTs.

5. Conclusions

Thin aluminum oxide films were prepared by exposing Al layers to ozone generated by UV lamp and/or high-voltage discharge. Four oxidation methods have been tested, namely the UV/ozone oxidation in ambient (UV-AA) and dry (UV-DA) air, UV/ozone oxidation combined with discharge-generated ozone in dry air (UV+O3-DA), and discharge-generated ozone in dry air (O3-DA). The AlO$_x$ layers were evaluated with spectroscopic ellipsometry, X-ray photoelectron spectroscopy and Fourier transform infrared spectroscopy. The capacitance and leakage current density of Al/AlO$_x$/Au and Al/AlO$_x$/C$_p$/PAu metal–insulator–metal structures were also measured and the relative permittivity of AlO$_x$ was extracted. Finally, the thin-film transistors based on pentacene and DNTT were fabricated to evaluate the suitability of the atmospheric pressure oxidation methods for organic electronics.

The lack of the high-energy photons during O3-DA oxidation led to a low relative permittivity and high leakage current density of the AlO$_x$ layer that rendered this method unsuitable for transistor dielectrics. Although the oxygen was incorporated into the film, the FTIR confirmed an increased concentration of subsurface oxygen while the XPS gave the highest portion of the unoxidized Al among all four methods. Overall, the presence of UV photons during the oxidation process promotes the diffusion of the oxygen and its incorporation into the AlO$_x$ lattice.

The AlO$_x$ layers prepared using UV lamp (UV-AA, UV-DA, UV+O3-DA) produced device quality oxides. Although there are minor differences in their properties, the 2-h oxidation produced AlO$_x$, films with thickness in excess of 7 nm, relative permittivity between 6.61 and 7.25, and leakage current density of $(1-7) \times 10^{-7}$ A/cm$^2$ at 2 MV/cm. All oxides contain some carbon impurities while the presence of –OH groups is below the detection limit.
