19	Abstract		
20			
21	The marine renewable energy industry is expanding globally in response to increased		
22	energy demands and the desire to curtail greenhouse gas emissions. Within the UK,		
23	Wales has the potential for the development of diverse marine renewable		
24	technologies, with a strong tidal range resource, areas of high tidal current energy, and		
25	a spatially limited wave energy resource. Targets have been set by the Welsh		
26	Government to increase the contribution of marine renewable energy to Wales'		
27	electricity generation, and the recent introduction of demonstration zones for tidal and		
28	wave energy aims to facilitate developers in device deployment. However,		
29	uncertainties remain about the potential impacts of devices, particularly for array scale		
30	deployments, planned at several sites, and for the extensive structures required to		
31	capture the tidal range resource. Here we review present knowledge of potential		
32	impacts, including physical, ecological and societal dimensions, and outline research		
33	priorities to provide a scientific basis on which to base decisions influencing the		
34	trajectory of Welsh marine renewable energy development.

36 Ecological impacts, Electromagnetic fields

37

38 1. Introduction

39

40 In response to international concern surrounding the impacts of climate 41 change, the UK government has committed to ambitious carbon emission reduction 42 targets of 34% by 2020, and at least 80% by 2050 [1]. To achieve these targets, it is 43 estimated that 30% of UK electricity will need to be generated from renewable 44 sources by 2020 [2]. Renewable energy from marine resources are expected to form a 45 key portion of this future energy mix—an assessment of the UK's theoretical marine 46 energy resource indicates a potential total annual energy yield of 285 TWh from 47 wave, tidal range, and tidal stream resources [3], compared to a current annual 48 electricity demand of approximately 303 TWh for 2014 [4]. However, this marine 49 resource is subject to both technical and economic constraints, and so the practically 50 exploitable resource will be considerably less.

51 In the UK, coastal waters around the country of Wales, bordered by the Irish 52 Sea to the north and west and the Bristol Channel to the south, hold a significant 53 portion of this UK marine energy resource; a governmental study assessing the entire 54 UK theoretical resource suggests approximately one seventh of the wave energy 55 resource, one quarter of the tidal range resource, and one third of the tidal stream 56 resource [3,5]. Recognising the value of this marine renewable energy resource, the 57 Welsh Government set ambitious targets, aiming to capture at least 10% of the 58 potential tidal stream and wave energy by 2025 (equivalent to 8kWh/day/person of 59 the mean consumption of 22kWh/day/person), and also committed to investigate 60 where tidal range technologies may be appropriate around the coastline [6].

61 There are substantial challenges associated with the technological 62 development and commercialisation of marine renewable energy that are required to 63 achieve the Welsh Government's targets, such as: 1) accurately quantifying the 'reallife' performance of individual devices, 2) uncertainty in terms of the outcomes of 64 65 consenting processes, political will and government subsidy, 3) potential ecological 66 impacts and unanticipated environmental effects, 4) public acceptance and community 67 engagement, and 5) cumulative effects when devices are installed at array scale. In 68 order to facilitate the work required of developers to address some of these issues, the 69 Crown Estate, as managers of the UK seabed, announced the lease of UK seabed

rights for six new wave energy and tidal stream 'demonstration zones' to third party
managers in July 2014. One wave demonstration site, and two tidal stream
demonstration sites are located off the Welsh coastline, in the waters surrounding
Pembrokeshire and West Anglesey respectively (Fig. 1).

Thorough scientific evidence to underpin policy decisions on MREIs (Marine Renewable Energy Installations) is incomplete—particularly for tidal lagoons where few comparable developments currently exist globally. The wave and tidal stream demonstration zones, together with proposed tidal lagoon developments, means that Wales has the full range of marine renewable energy technologies under active development, and contains the sites where several developers plan to scale up from single test devices, to multiple device demonstration sites and commercial arrays.

81 Thus, in addition to increasing our knowledge of 'primary' impacts, there is 82 the potential for cumulative impacts and multiple device/array interactions, which are 83 difficult to predict on the basis of existing data, and tend to be based exclusively on 84 theoretical modelling studies [e.g. 7]. The impacts from proposed MREIs are wide-85 ranging, and encompass a mixture of positive and negative socio-economic impacts 86 (e.g. combined recreational and aquaculture use, coastal defence, altered coastal 87 aesthetics), as well as potentially deleterious environmental effects (e.g. sediment 88 transport). These potential impacts require careful consideration, as Welsh coastal and 89 inshore areas have a wide range of sites designated for species and habitat 90 conservation goals, as well as heritage and aesthetic values, and consideration is being 91 given to expanding existing Marine Protected Areas (MPAs; Fig. 2).

Here, following a brief description of current developments we outline current knowledge of the likely impacts of marine renewable energy developments, and from this highlight research gaps which should be addressed to reduce uncertainty and inform the decision making and consenting process within Wales.

96

97 2. Marine renewable energy developments

98

99 2.1. Tidal Stream

100

101Several areas around the Welsh coastline have a sufficiently powerful tidal102stream resource to be considered as sites for tidal stream devices. These are

103 concentrated within narrow channels and around headlands, where the constriction of

104 flow accelerates the tidal current (such as to the West and North of Anglesey and off 105 the Pembrokeshire coastline) and can be seen in Figure 1. The Crown Estate has 106 estimated that each of these areas has a potential installed capacity of 2–4 GW, but 107 research suggests that with technological developments the tidal-stream energy 108 resource could be much higher if deeper water and lower flow sites were developed 109 [5]; such as the partial amphidromic point off Ireland (see Fig. 3).

The predictability of tidal stream energy is highly attractive to developers, and eases grid management issues compared to other stochastic renewable energy forms [8]. Potential TEC deployments around Wales include several forms of device, such as horizontal/vertical axis turbines, oscillating hydrofoils and tidal kites, as reviewed in [9]. Although studies to predict performance have been carried out for many of these devices, optimal siting, resilient design, and the interaction between the device, the resource, and the environment are topics of active research [7,8,10,11].

117

118 2.2 Tidal Range

119

120 Substantial potential exists for tidal barrages and tidal lagoons to contribute to 121 renewable electricity generation within the UK. There is particular focus on Wales, 122 because of the large tidal ranges in both South Wales [>12 m; 12], and in North Wales 123 [>8 m; 13], and the potential to contribute to tidal phasing solutions for constant 124 electricity production in conjunction with tidal-stream energy [5]. By far the largest 125 potential contribution of marine renewable technologies to the UK's energy demand 126 could be from tidal barrages—at least 10%, or ~22 GW could come from the Severn 127 Estuary alone [12]. However, barrage design proposals for the Severn Estuary, 128 developed since the 1970s [14–21], have failed to gain governmental support, due to 129 significant environmental implications and high capital cost [22,23]. The Severn Tidal 130 Power Feasibility Study concluded that the obstacles to a Severn Barrage scheme 131 were too great for public investment [1,24]. Therefore, we will limit our scope to 132 reviewing tidal lagoons, although the processes and impact of lagoons and barrages 133 are often intertwined.

The indicative annual energy resource from tidal lagoon schemes has been
estimated as 2–4 GW in the Severn Estuary area, and 4–8 GW along the North Wales
coastline [3,7]. There is spatial variability in the phasing of tidal range around Wales;
north and south coasts are approximately 4 hours out-of-phase with one another (Fig.

138 3), meaning that energy intermittency issues throughout the day could be minimised if 139 lagoons were strategically constructed both in the north and south. However, variation 140 in power generation also exists over the lunar cycle (spring and neap tides). A 141 proposed tidal lagoon in Swansea Bay [25,26] has been granted development consent 142 by the Secretary of State for Energy and Climate Change in June 2015. The lagoon 143 development would be projected to have a rated capacity of 320 MW by 2018. Plans 144 also exist for tidal lagoon developments at several additional locations around the 145 Welsh Coastline (Fig. 1). A much larger proposed tidal lagoon between Cardiff and 146 Newport would have an installed capacity of 1.8 to 2.8 GW, dependent on final 147 design [27,28].

148 Several developers have interest in areas along the North Wales coast as sites 149 for tidal lagoons, where spring and neap tidal ranges are approximately 7.5 m and 150 4 m, respectively [>12 m; 12,29]. Through an initial model study of large-scale 151 lagoon designs in North Wales, Angeloudis et al. [29] predicted that power generation 152 in this region is not plausible during neap tides, because of the small tidal range. 153 Angeloudis et al. [12,29] also calculated that, for their lagoon designs, approximately 154 38% of the annual potential energy could be harnessed, acknowledging the effects of 155 intertidal hydrodynamics and turbine/sluice gate specifications. Moreover, the 156 harnessed energy could be reduced further if other lagoons were built in the vicinity.

157

158 2.3 Wave Energy

159 The theoretically extractable annual mean UK wave power resource has been 160 estimated as 43 ± 4 GW [30], with long-term annual mean wave power levels along the western UK coastline ranging from 25–75 kW m⁻¹ [31,32]. The highest 161 162 concentrations of wave power around the Welsh coastline are in areas to the 163 southwest, which are exposed to the Atlantic Ocean (Fig. 4). The UK Atlas of Marine 164 Renewable Energy Resources, estimates the theoretical annual mean wave power density to be 15–20 kW m⁻¹ close to the Pembrokeshire coastline, with areas further 165 offshore approaching 30 kW m⁻¹; however the spatial and temporal resolution of the 166 167 data used to produce these estimates is very coarse. Indeed, inter-annual and inter-168 decadal variability of the resource needs to be considered to enable optimal site 169 selection and accurate device performance projections by developers [33]. 170 Wave Energy Converter (WEC) devices are based on a wide range of

171 operating principles, as reviewed in [34,35], with varying extraction efficiencies, and

172 optimal location in terms of depth and wave climate. Devices may be broadly 173 categorised according to distance from the shoreline; either onshore, nearshore or 174 offshore [32], with associated differences in both engineering challenges and performance parameters. Accurate characterisation of WEC device behaviour is 175 176 needed for accurate technical resource estimates [36,37], and essential in determining 177 the potential for WEC devices to generate electricity in Welsh coastal areas. 178 There are three sites currently undergoing feasibility studies for the 179 deployment of WEC technology in Wales, all off the south Pembrokeshire coast, and 180 in close proximity to Milford Haven port. The Crown Estate wave demonstration zone managed by WaveHub is a 90 km² area sited \sim 20 km from shore in 60 m water depth. 181 182 Wave Dragon Limited have proposed a smaller site in similar depths to the west of 183 the demonstration zone, whilst Marine Energy Limited have proposed a nearshore site 184 off St Govan's Head. No devices are presently deployed; however, Swansea-based Marine Power Systems have planned the testing of a scale version of their Wavesub 185 186 device at the Haven Waterway Enterprise Zone in 2017, prior to a full-scale device 187 being tested in the demonstration zone in 2019.

188

189 **3. Physical impacts and research priorities**

190

191 *3.1 Tidal stream technology*

192 Recent studies have indicated the likelihood of environmental impacts and 193 changes to hydrological regimes associated with extracting energy from the tides 194 [10,38,39]. The primary impacts of TECs are the impacts of the structure and the 195 energy extraction on hydrodynamics and morphodynamics (sediment transport). The 196 physical presence of a TEC and its foundations alters near-field hydrodynamics and 197 sediment dynamics during both installation and operational phases. The turbine 198 motion of tidal stream devices also impacts turbulence and dissipation in the area 199 surrounding a device [40].

200

Power extraction by TECs reduces the kinetic energy of the tidal currents in
comparison to the undisturbed resource. Extracting tidal stream energy can also
influence water surface elevations, although this impact is thought to be minimal [7].
Through alteration of the tidal currents, tidal steam energy extraction has the potential
to cause spatial and temporal variations in sedimentation and erosion rates [39]. The
magnitude of this impact on sediment dynamics increases with the degree of tidal

asymmetry at the point of extraction [39], therefore the magnitude and nature of tidal
asymmetry should to be considered alongside the magnitude of the tidal currents
when considering potential sites for situating TECs.

210

211 The potential for full-scale (300MW) arrays of TECs to change larger-scale 212 far-field sediment dynamics, such as the maintenance of headland sand banks has 213 been identified [7]. Sand banks play an important role in coastal defence through 214 depth induced wave breaking, and can influence the condition of adjacent beaches 215 through sediment exchange [7,41]. Recent modelling studies have begun to quantify 216 the magnitude of impacts on the sedimentary processes affecting sand banks, and 217 indicate that 'first generation' (<50 MW) TEC array sizes would result in sedimentary 218 impacts within the bounds of natural variation at tidal sites off northwest Anglesev 219 [42].

220

221 The near-field effects of TECs on flow can be modelled numerically or can be 222 observed in physical laboratory experiments. However, there is considerable 223 uncertainty regarding the magnitude of these effects, as the impacts of prototype 224 devices (at pilot scales) may not translate to the impacts from commercial-scale 225 arrays. Although some modelling studies exist [7,11,43], many impacts from scaling 226 up test devices into commercial-scale arrays remain unknown, as the interactions 227 between the impacting processes and the cumulative effects of tidal energy extraction 228 are highly site-dependent. For example, for a single TEC operating in a steady flow, 229 there is a deceleration of the tidal current speed immediately upstream as well as 230 downstream of the device, with accelerated tidal current speed (and turbulence) 231 around the device, and a turbulent wake downstream. Moreover, energy extraction in 232 resource models tend to be implemented as depth-averaged processes, and as the 233 interaction between devices and the resource are non-linear, three-dimensional, and 234 with temporal variability to current speed and turbulence; hence much more research 235 is required to resolve turbine behaviour in hydrodynamic models before impacts can 236 be fully resolved.

237

238 3.2 Tidal lagoons

239

240 *3.2.1 Inside lagoons*:

241 A primary impact of the physical tidal lagoon structure is that natural tidal and 242 coastal currents will decrease or be completely absent (during the water holding 243 periods) within the lagoon [13,44]. Most importantly, reduced energy and tidal 244 pumping inside the lagoon will alter sedimentation patterns and sedimentary features, 245 with the most obvious effect being scour occurring near turbines and sluices, and 246 siltation elsewhere [45]. Vertical mixing will be reduced (away from turbine wake), 247 hence concentrations of suspended sediments and other materials will be reduced, and 248 light penetration and stratification will be increased; all of which could result in water 249 quality problems [43,45]. For example, there may be a build-up of physical and 250 chemical contaminants due to reduced flushing, or re-suspension of contaminated 251 sediments in regions of scour [45]. In addition, increased light may stimulate primary 252 productivity increasing the risk of eutrophication and altering nutrient flow as 253 phytoplankton deposition occurs [45].

254

By concentrating turbines in one section of the lagoon wall (sometimes called the power house), counter-rotating eddies may form in the turbine wake [14,44], which could impact the marine environment resulting in localised sediment resuspension, scour, and water quality impacts. Instead, Falconer et al. [14] recommended evenly spacing turbines throughout the whole lagoon structure. In practice, this may not be feasible due to bathymetric or other constraints.

261

262 Lagoons may cause a loss of intertidal areas within the structure, since the 263 surface-level range will be reduced, compared with the natural tidal range. One 264 potential benefit will be reduced coastal flood risk for lagoons which are connected to 265 land—a circumstance that is particularly relevant to the North Wales coast [13]. 266 During extreme storm events, for example, turbines could be shut off to prevent flood 267 flow impacting the coastline within the lagoon wall. A detrimental environmental 268 effect of a reduction of intertidal area is the loss of intertidal habitats for resident and 269 migratory species; for example, loss of salt marshes, soft sediment biota, rocky shore 270 species, and Sabellaria biogenic reefs. Lagoon or barrage structures in estuaries 271 would, on the whole, negatively impact on habitat conservation, water quality, and 272 ecosystem services [45]. Despite this, tidal ranges and potential energy yield are 273 maximal in estuaries, thus ultimately benefitting the wider environment through 274 reduced carbon emissions [45]. Therefore, tidal range development siting should

275 carefully weigh up the resource and anticipated environmental interactions,

276 particularly for estuarine locations.

277

278 *3.2.2 Outside lagoons*:

279

280 The alteration of the natural physical environment outside of lagoons will 281 depend on the regional hydrodynamics and atmospheric conditions, local topography 282 and bathymetry, the design of the lagoon, and the operational specifications of the 283 lagoon [13]. Clearly, the larger the area of the lagoon, the greater the power output 284 and the greater the alterations to the physical environment [44]. Processes that are 285 likely to be impacted are scour near the lagoon, sediment supply to beaches and sand 286 banks/bars, and wave reflection/diffraction. Sediment starvation to sand banks, sand 287 bars, and beaches may impact the ability of these features to absorb the energy of winter storms, protecting the coast from wave erosion [7,42]. Sand banks/bars are also 288 289 important nursery and breeding grounds for many fish species [45].

290

291 Away from the turbines (i.e., > 50 km), the hydrodynamic effects are likely to 292 be minimal, although simulated tidal range increased in Boston, USA, by a few 293 percent, as a result of possible lagoon designs located within the Bay of Fundy, 294 Canada—simulation with sluice gates always closed (i.e., no power generation) 295 produced maximum change in tidal range [44]. Therefore, as Wolf et al. [45] also 296 alluded to, far field flood risk could be increased due to large-scale lagoon structures. 297 Hydrodynamic impacts of lagoons in near resonant systems, such as the Severn 298 Estuary, are likely to be pronounced [44]; affecting flood risk both in the near-field 299 (due to altered sedimentation and beach morphology) and in the far-field (due to 300 altered tidal regimes). Lagoons may also affect the strength of residual currents and 301 positioning of frontal systems, where stratified and mixed waters meet, attracting 302 feeding fish and seabirds [46] —although this risk is thought to be small [45]. 303

304 *3.2.3 Research priorities*

305

There is an urgent need for better characterisation of the tidal resource, which includes the interactions of the resource with proposed lagoons and their surrounding environment. Through hydrodynamic modelling, the natural (pre-lagoon) environment needs to be better characterised: wave and storm climates and 310 seasonal/inter-annual variability, residual sediment transport pathways, and turbulent

mixing rates, with particular attention paid to potential extreme conditions and climatechange.

313

314 Numerical models which include a variety of lagoon designs and turbine 315 parameterisation options are being refined [e.g. 44]. Importantly, the shape of the 316 embayment and the number and position of turbines and sluice gates can be optimised 317 to maximise yield and minimise environmental impacts. Future modelling research 318 should, therefore, focus on design optimisation that yields sufficient (rather than 319 maximum) electricity generation, whilst minimising undesirable environmental 320 consequences—especially concerning sediment dynamics and water quality. Models 321 will require repeated bathymetric surveys and time-series wave and current data for 322 validation.

323

324

325 *3.3 Wave energy converters*

326

Several model studies have demonstrated significant effects of WECs
on the wave climate which, at significant scales of electricity generation, is likely to
impact nearshore processes. Although initial work applied constant transmission
coefficients across the entire frequency spectrum to simulate energy extraction [47],
studies have increasingly incorporated the impacts of WEC power performance
[48,49], device size [49], and WEC array configuration [50] on downstream wave
propagation.

A concern identified early in the development of WEC technology is the likelihood of coastal erosion patterns to change, impacting beach morphology and shallow water bathymetry in adjacent coastal areas [31,51]. More recently the consideration of WEC arrays for coastal protection purposes has been suggested [52,53], a role which is of increasing importance under climate change-driven future scenarios of coastal flooding and storminess [e.g. 54–56].

Surf zone sandbars reduce sediment erosion on beaches by depth-induced
wave breaking [57]; hence, when beach morphology is in equilibrium, this erosion
may be balanced by slower onshore migration between storms from lower amplitude
dispersed swell waves [57]. Therefore, WECs may alter beach morphology processes
[52,53], and research indicates their potential for coastal defence [53].

345	Future simulation of WEC impact research should continue to address the
346	consideration that WECs do not remove wave power equally across the frequency
347	spectrum. Porter et al. [58] highlight some of the modelling studies that have made
348	efforts to address this issue but note that observational validation is lacking. An
349	additional uncertainty within modelling studies is whether devices will be operational
350	during storm events, as WEC may be switched into 'survival mode' during intense
351	storms to avoid device damage, with the result that a greater proportion of wave
352	energy reduction may occur outside of winter months [50]. The development and
353	implementation of WEC array modules for spectral wave models such as SNL-
354	SWAN [49,58] will prove a useful tool for assessing environmental impacts,
355	particularly when combined with realistic device power transfer functions and wave-
356	current interaction [25,48]. An additional challenge is to increase the ability of
357	morphodynamic models to accurately predict the erosion or accretion/post-storm
358	recovery of beaches [59], The potential impacts of WEC deployments at sites off the
359	Welsh coastline on sand banks and beaches should be considered within the context
360	of our present understanding of the natural variability of such features [60-62].
361	
362	
363	4. Potential ecological impacts and research priorities
364	
365	4.1 Benthic habitats and species
366	
367	A primary impact of the construction of Marine Renewable Energy Devices
368	(MREDs) will be the alteration of the benthic habitat within the construction footprint
369	of the device, and any associated cabling routes [63]. However, impacts on the
370	benthic environment are not limited to the physical footprint of devices, as changes in
371	current regimes and associated sediment dynamics have the potential for far field
372	effects such as alteration of food supply, and smothering or increased erosion of
373	sediment [63]. As MREDs scale up from the single device, to the array scale
374	deployments planned around Wales, the potential for habitat fragmentation, a major
375	cause of biodiversity loss within marine environments [64], becomes more relevant.
376	
	Whilst broad scale habitat knowledge for Weish coastal areas exists, little is presently
377	known about the finer scale patterns of benthic species distribution within planned

beam echosounders for acoustic classification of benthic habitat types within MREIsaround Wales.

381 Potential benefits to benthic biodiversity have also been outlined for MREIs 382 [65]. The main mechanisms for this benefit are: 1) the artificial reef effect [66–68], 2) 383 the ability of MREI sites to function as de-facto marine reserves, where fishing 384 activities such as dredging are excluded [65,69,70]. Device structure and foundations 385 also introduce a hard substrate into areas where it never previously existed. The 386 assemblage of species that artificial structures support, are often different from those 387 occurring on surrounding substrates [71]. In particular, opportunistic species are likely 388 to dominate, and invasive species for which a viable larval supply exists may rapidly 389 colonise the structures [72]. Whilst existing evidence for this comes from Danish 390 windfarms [73], MRED structures in Wales may experience the same effect. Where 391 numerous MREDs are present in the marine environment, the structures may act as 392 stepping-stones for marine invasive species [74]. Of particular concern in Wales is the 393 presence of *Didemnum vexillum* in Holyhead harbour [75,76], and *Crepidula* 394 fornicata in Milford Haven [77], both important areas for boat traffic associated with 395 MREIs in Wales.

396

397 4.2 Direct collision and physical interaction

398

399 *4.2.1 Seabirds*

400 Welsh coastal waters support diverse seabird communities during summer 401 months when large breeding assemblages in the south-west e.g. Grassholm, Skomer, 402 Skokholm and Ramsay Islands [78], exploit waters spanning from the northern Celtic 403 Sea to the northern Irish Sea [e.g. 79–81]. In particular, the populations of Manx 404 shearwaters Puffinus puffinus, and northern gannets Morus bassanus on 405 Skomer/Skokholm and Grassholm respectively are internationally important. There 406 are also sizeable breeding assemblages spread across Anglesey, and Bardsey Island in 407 the north [78]. In addition, certain regions appear important outside of summer 408 months, most notably southwest Wales for common guillemots Uria aalge and lesser-409 black backed gulls *Larus fuscus* [82]. However, the close proximity of sizeable 410 breeding assemblages in Pembrokeshire, Anglesey and Bardsey Island to areas 411 suitable for tidal stream and wave energy extraction create the possibility of high 412 overlap between distributions of seabirds and array installations [83], and it is during 413 these months when risks are probably higher.

415 Due to the submerged, or semi-submerged, manner of tidal stream turbines 416 and WEC, these installations are most likely to threaten seabird species during their 417 foraging activities, when species utilise the water column [84]. For submerged tidal 418 stream turbines, any interactions will be constrained to species consistently foraging 419 at depths greater than 5–10m (auks, divers and cormorants) using plunge diving 420 techniques [85]. Due to the dynamic manner of turbine blades at these depths, there is 421 a possibility of negative impacts through collisions [86]. For semi-submerged WEC 422 and tidal stream turbines, interactions are also likely among species foraging on the 423 surface and upper water column (gannets, gulls, terns, skuas, shearwaters and storm 424 petrels) using plunge-diving or pecking techniques [85]. Nevertheless, the benign 425 manner of components at these depths mean that risks of negative impacts are 426 probably minimal; instead, some positive impacts may be seen-for example, species 427 have been seen exploiting WEC as novel roosting sites. Therefore, negative impacts 428 associated with physical interactions are most likely to involve pursuit-diving seabirds 429 and moving components of tidal stream turbines, and it is this threat which demands 430 most attention.

431

414

432 As with most taxa, levels of risk probably vary among species. Despite their 433 shared exploitation of high-energy habitats, species generally occupy different 434 microhabitats within these sites [87,88]. Those tending to exploit areas of maximum-435 energy within these habitats are more likely to encounter devices [89]. The possibility 436 of collisions could then depend upon species' underwater manoeuvrability and speed. 437 The principle differences in diving behaviour occur between wing-propelled auks and 438 foot-propelled cormorants/divers. The use of wings and feet for diving propulsion is 439 considered as a trade-off between speed and manoeuvrability; auks are capable of 440 higher speeds but cormorants/divers exhibit higher manoeuvrability. However, how 441 these differences translate into collision risks remains unknown [84].

The possibility of collisions also depends upon a species' tendency to exploit either benthic or pelagic prey, with the former associated with deeper, lengthier and riskier dives [86]. Levels of risk also vary within a species over space and time—for instance, species' tendency to exploit areas of maximum energy, and therefore interact with installations, could vary seasonally due to differences in their core foraging strategies, or migratory movements from inshore into offshore habitats during non-breeding seasons [88]. Consistent differences in foraging strategies among

449 sites, perhaps linked with local resource availability or 'behavioural cultures', could 450 further determine a species' likelihood of interacting with devices. In one such 451 example, cormorant species exploit areas of relatively low energy within some sites, 452 but areas of maximum energy within others [88,90,91]. In addition to differences 453 among and within species, levels of risk almost certainly vary among devices 454 depending on their specifications, Potential risk from tidal kites, for instance, would 455 probably vary greatly from conventional tidal stream turbine designs due to their 456 fundamental differences in design and operational dynamics.

457

458 The aforementioned variations in levels of risk create a need to understand 459 behaviours at a species, seasonal and site-specific level. Quantifying a species' 460 relative use of a high-energy site, and then use of areas suitable for installations 461 within the site, forms one component of risk assessment [89]. Use of existing at-sea aerial/vessel surveys over appropriate regions, in conjunction with targeted surveys 462 463 within the focal site, can help address these questions [89]. Quantifying foraging 464 behaviours immediately around devices is another component of risk assessment. 465 Recording such behaviours provides challenges due to the inherent difficulties in 466 recording fine resolution behavioural information within very specific locations, 467 particularly in the demanding conditions within high-energy sites [89]. This explains 468 why the influence of diving behaviour on collision risk remains largely unknown [84]. 469 However, novel technologies using sub-surface hydroacoustic methods alongside 470 devices are overcoming these issues [92]. What is clear, however, is that there are 471 large differences between tidal/wave and offshore wind electricity generation 472 concerning the spatial extent and resolution of data needed to assess potential impacts 473 on seabirds. The need for high-resolution data at fine spatial scales within relatively 474 small sites means that targeted and novel approaches are needed, rather than a simple 475 adaption of surveying techniques commonly used for offshore wind covering much 476 larger scales and areas.

477

478 *4.2.2 Fish*

479

Within the UK, migratory fish have been highlighted as the main concern in
regards to fish interactions with MREDs [93]. However, various fish species also
contribute to the diet of diving seabirds and marine mammals, and so are linked to
top-predators that are identified as potentially vulnerable to MREDs. Physical injuries

484 to fish caused by mechanical strike, shear and cavitation are the principle risks 485 identified [94,95]. These potential impacts are shared by most tidal turbine 486 technologies but the risk will differ between 'open ocean' tidal stream turbines, and 487 those that are within an enclosing structure in a tidal range development or WEC. 488 Tidal kite projects will also have broadly similar potential impacts but may be higher 489 risk due to the kite device moving through the water at several times the ambient 490 current velocity [96]. WECs are considered to be of comparatively lower concern 491 based on designs presently proposed [97], but will need to be evaluated for each 492 specific design proposed for deployment and how potential fish aggregation may 493 modify any collision risk with marine mammals and diving seabirds. Designs may 494 cause avoidance due to device movement and associated noise, or alternatively some 495 surface floating devices may function as *de-facto* fish aggregating devices [98].

496

497 Preliminary studies on horizontal axis turbines indicate that fish are able to avoid 498 turbines with higher avoidance rates when fish are in schools and during the day, due 499 to social behaviour and visual avoidance [99]. However, within three metres of a 500 turbine avoidance was low, with only 1% of fish observed not passing through the 501 turbines [99]. A major concern surrounding tidal lagoons is therefore fish impacts, 502 which may not easily bypass the turbines within the lagoon wall. Efforts to minimise 503 this risk require thorough consideration of device design [13]. For example, it has 504 been suggested that large-diameter turbines, with slower rotor speeds than small-505 diameter turbines, are likely to be less hazardous to fish [100]. In addition, two-way 506 generation turbines have been suggested to minimise environmental impact [20], and 507 fish passes for migratory fish could be incorporated into MREDs [45].

508

509 Fish species composition and abundance vary spatially between different tidal 510 stream project sites, and temporally over seasonal or diurnal cycles, which means site 511 specific studies with control sites monitored over an appropriate timescale are 512 necessary to assess potential device impact. The potential interactions between fish 513 and tidal turbines have been identified as a research gap for tidal stream power 514 generation in the UK as a whole, and Wales in particular [86,101]. Gaining a more 515 thorough understanding of the ecological function of high tidal current areas and those 516 surrounding tidal lagoons for fish species in Welsh coastal areas is necessary before 517 potential impacts can be fully understood and mitigated appropriately.

519 Effective methodologies to study fish interactions with wave and tidal devices are 520 still being developed. Both static and mobile acoustic surveys have been employed at 521 locations in North America, together with acoustic tagging and video methods at 522 some sites [99,102]. Acoustic transmitting tags may provide information on the 523 broader spatial dynamics and migration routes of fish species whose ranges intersect 524 with the proposed MREI sites around Wales. Moored devices that collect data on the 525 presence and behaviour of fish and plankton, in addition to ambient noise before, 526 during, and after construction are likely to be useful tools, not least due to the 527 difficulties of conducting regular boat based observations in high-energy 528 environments.

- 529
- 530 *4.2.3 Marine Mammals*
- 531

532 Welsh coastal waters support a number of marine mammal species including 533 both resident and transient populations. Eighteen species have been recorded since the 534 1990s, and five of these are commonly encountered [103]. The extent of collision risk 535 with marine mammals is currently unclear and it is likely to be species and site-536 specific, and further influenced by device design. Turbines used in tidal stream and 537 range technology are likely to pose more of a risk than WECs. However, fast-moving 538 animals that surface regularly could be vulnerable to collision or entrapment from 539 WECs.

540

541 Present knowledge of collision risk is limited and focuses on modelling the 542 encounter rate between marine mammals and turbines based on physical 543 characteristics of turbines, physical and behavioural characteristics of animals and 544 local density estimates [86]. However, in many cases, validated input parameters are 545 not available and therefore the accuracy of the model is uncertain. As part of recent 546 developments at MRED test sites, mitigation procedures including using active sonar 547 to detect mammals and an initial shut down clause when mammals were in close 548 proximity were in place during device operation [71,104].

549

The first tidal turbine in Wales has been installed in Ramsey Sound,
Pembrokeshire. Mitigation measures during operation will include the use of active
sonar, marine mammal observers and passive acoustics for tracking the fine scale
underwater movements of mammals around tidal devices [105]. As so few MREDs

are in operation, opportunities to collect empirical data on marine mammal impacts are limited. In Wales, where a number of MREDs are in the planning stages, there is an opportunity to focus efforts in collecting pre-construction site-specific baseline data relevant to assessing the risk of impacts. To refine assessments of collision likelihood, finer-scale studies into the distribution (both horizontal and vertical) of marine mammals within sites are required, focussing on how distribution and density vary with current speeds and in relation to site physical features.

561

High-energy areas are challenging field sites to study marine mammals due to turbulence, strong currents and noise. In some cases traditional research methods should be adapted to better suit the difficult nature of these locations, such as developing streamlined housings for moored acoustic recorders [e.g. 106], or drifting devices [107] to reduce current noise. During vessel-based surveys it may be necessary to alter transect design to reduce the bias of strong current direction affecting speed over ground [107,108].

569

570 There are further challenges relating to collecting fine-scale data such as the 571 availability of associated data collected at the required scale and the spatial precision 572 of locating animals. Regarding the latter, hydrophone arrays capable of tracking 573 echolocating animals in 3D may be suitable [108]. Recent advancements have also 574 been made to design arrays that will function better in high-energy environments and 575 with relatively low cost [109].

576

577 Visual methods can be useful for some species, such as baleen whales, which 578 do not echolocate. Some odontocetes may not vocalise as frequently or may be easier 579 to detect visually compared with other species such as harbour porpoise (Phocoena 580 phocoena). Many development locations, including tidal lagoons and near-shore tidal 581 stream sites may be well suited to land-based visual surveys. A long-term dataset 582 exists from land-based watches at Ramsey Sound [110], and at the tidal stream site at 583 the Skerries, a pioneering method is being developed to calculate absolute density 584 estimates from the coastline.

585

It is also vital to assess population effects of collisions with MREDs which may occur in Welsh waters. However, without robust density estimates relative to the development site it's not possible to predict the consequences of fatal collisions on a 589 population. Traditionally, density estimates have been calculated using a distance

sampling protocol, particularly vessel-based line-transect surveys. In recent years, the

technology of passive acoustic arrays to estimate density has been developed,

bowever, there are difficulties associated with obtaining density estimates with

593 sufficient power to detect trends for highly mobile species in relatively small areas

such as the Welsh Tide and Wave Demonstration Zones.

595

596 4.3 Noise and electromagnetic field effects

597

598 There is growing awareness of the potential impacts of anthropogenic 599 underwater noise on the marine environment, as the role of sound in the life cycles of 600 key marine organisms is increasingly apparent [e.g. 111,112]. The generation of 601 underwater noise is common to all of the forms of MRED envisaged along the Welsh 602 coastline. In particular, the construction phases will share the features of increased 603 boat traffic, and the noise and vibrations generated during device installation. For tidal 604 range technology the construction phase will be extensive and is likely to constitute a 605 more chronic disturbance than the shorter duration high intensity activities, 606 particularly pile driving, which will be required for several forms of tidal stream and 607 wave energy devices. During operation, underwater noise will be generated by tidal 608 turbines, and by some wave energy converters, however potential impacts may be 609 reduced due to the ambient noise levels in high current areas such as the West 610 Anglesey Tidal Demonstration Zone, which tend to be elevated due to fast flowing 611 water and sediment movement. Conversely, if noise levels generated during MRED 612 operation are low, mobile species may not be alerted to the risk of collision until close 613 proximity to a MRED.

614 Anthropogenic noise is a particular concern for cetaceans, given their noise 615 sensitivity associated with employing a wide band of acoustic frequencies for 616 navigation, communication and foraging. A key issue is whether exposure to noise 617 results in behavioural changes causing displacement from key habitats or disturbance 618 at breeding or social activity sites that will affect cetacean populations in the long-619 term [111]. Initial studies investigating generation of noise by wave and tidal devices 620 suggest that displacement effects may be small or unlikely due to the low received 621 levels in comparison with ambient noise [104,113]. However, these are specific to 622 single devices and there is a requirement to consider scaled up effects relating to 623 commercial-scale arrays.

625 Whilst primarily concentrating MRED deployment within Demonstration 626 Zones around Wales may be beneficial in reducing the spatial extent of noise 627 disturbance, a research challenge is determining if potential avoidance of these sites 628 by large mobile species translates into population level impacts. Behavioural studies, 629 encompassing both observational and active behavioural response can reveal reactions 630 to a disturbance. This becomes highly useful if links can be made between 631 behavioural change and individual health, allowing these findings to be modelled into 632 population consequences [114,115]. In some cases no behavioural response will be 633 observed, however, this does not necessarily mean an absence of disturbance capable 634 of influencing survival. Similarly, a behavioural change may indeed be recorded but 635 which has no significant consequences relating to the health of the individual 636 [114,115], therefore, establishing the links between behaviour and effects on survival 637 and fecundity should be a research priority.

638

624

639 Electromagnetic field (EMF) emissions along cabling routes are an additional 640 consideration for tidal stream and wave energy sites around the coast of Wales. 641 Proposed tidal lagoon developments will not require electricity to be transported from 642 offshore locations, as the current proposals are that the cable route will run underneath 643 the lagoon boundary, with EMF emissions calculated as $\sim 100 \mu$ T at the breakwater 644 surface [116]. Due to the rapid reduction in EMF strength with distance in water, 645 emissions will rapidly fall to background levels [~50µT: 117], and any potential 646 impact will be localised to the lagoon breakwater.

EMF emissions can be detected by a variety of marine life, but fish species which use magnetic fields for orientation, and the electrosensitive elasmobranchs are most vulnerable to disturbance [118]. A UK-wide concern for diadromous fish species is the potential for migration routes to be disrupted where these interact with cabling routes [119]. For Wales, migratory stocks of the European eel (*Anguilla Anguilla*), Sea Trout (*Salmo trutta L*), and Salmon (*Salmo salar*) may interact with proposed cabling routes and tidal lagoons structures [120–122].

Whilst existing evidence for the impacts of EMF produced by cabling on fish distributions comes from offshore wind farm sites [e.g. 123], comparable cabling specifications and deployment methods will be utilised in offshore wave or tidal installations. Recent studies have noted that research to determine the potential impacts of cabling on elasmobranches is lacking at existing UK wave energy sites 659 [69], and have further suggested the potential for strategic management of MREI with 660 respect to their possible impacts on elasmobranchs for some areas of the UK [124]. 661 An issue that requires further research within both Welsh and broader UK waters is 662 the potential for cumulative developments to create barriers to migration or usage of 663 areas with important functioning to elasmobranch populations. Research in North 664 Wales will focus on the Holyhead Deep, off the west coast of Anglesey, an area 665 targeted by recreational anglers for elasmobranchs, in particular the UK priority 666 species Tope (Galeorhinus galeus), and also an area where TEC device deployment is 667 planned.

668

669 5. Water quality impacts

670

MREI installed in the marine environment will primarily alter water quality through the introduction of new contaminants or the re-mobilisation of existing contaminants. The extent of these environmental effects will depend on device characteristics, alterations to the local hydrodynamic regime, site geomorphology, and the marine species present within the site. Both near and far-field water quality issues may result from MREI, but are likely to be highly site specific [18,125,126].

677

678 5.1 Construction and decommissioning phases

679 The deployment of MRED requires usage of a range of compounds to enable 680 devices to function in the harsh maritime environment, for example gearbox 681 lubricants, anti-corrosion coatings, and anti-fouling paints [127]. Experiments carried 682 out in laboratory settings with some of the chemicals within these compounds have 683 demonstrated detrimental impacts on marine biota, and whilst low concentrations of 684 such chemicals are unlikely to induce mortality, there is potential for sub-lethal 685 effects on the sensory systems, growth and behaviour of marine species [128]. Over 686 longer timescales low concentrations could result in the bioaccumulation of toxins 687 including heavy metals in sediments surrounding MREI, and ultimately throughout 688 the marine food web [129]. Over shorter timescales the increased boat traffic 689 associated with device installation poses a risk to water quality due to small, 690 potentially frequent fuel leakages. Larger, infrequent releases of chemicals used for 691 maintenance may occur due to accidents or spillages, resulting in localised 692 behavioural or toxicity impacts to marine biota [129].

693 Potential impacts resulting from the installation phase also need to consider 694 the subsea cabling required to bring electricity onshore. The techniques presently 695 employed to bury subsea cabling cause sediment re-suspension and consequently, any contaminated sediments will be locally re-mobilised, and dependant on sediment size 696 697 and hydrodynamic regime, may be transported further afield. A decommissioning 698 phase that includes the removal of subsea cabling will again disturb any sediment in 699 the surrounding area; contaminants that have accumulated along the cabling pathway 700 will be re-mobilised. Device decommissioning may also cause water quality issues if 701 toxins are released from compounds contained within the device structure e.g. the 702 lubricants and hydraulic fluids used in gearboxes, bearings and rotor shafts.

703

5.2 Contaminant and water quality issues during operation

705

706 Tidal energy devices alter the hydrodynamic regime at the installation site; in 707 sites with fine sediments, increases in water turbulence may lead to localised 708 increases in turbidity. In areas with existing sediment contamination, increased 709 turbidity is likely to lead to contaminant re-suspension. The altered hydrodynamic 710 regime will influence the spatial scale of the impacts from re-suspended contaminants, 711 devices located offshore are at less risk since contamination reduces with increasing 712 distance from the shore, due to greater dilution capacity in the open ocean [130]. In 713 comparison, devices near shore, in areas where fine sediment deposition occurs and 714 land based sources of contaminants are more common, pose a greater risk of 715 contributing to and remobilizing contaminated sediments.

716

717 Tidal energy harvested through the impoundment of water in a tidal lagoon 718 impoundments operation has high potential for water contamination issues, dependent 719 on the location of the lagoon development. If the area enclosed by a lagoon already 720 receives contamination from different sources, impounding the water for part of the 721 tidal cycle will cause changes to the tidal and residual flows. The amount of water in 722 circulation will be reduced when the tidal flows and therefore flushing rates are 723 reduced. With reduced resuspension the levels of suspended particulate matter will 724 drop, resulting in deposition of both fine sediment and any associated chemical 725 contaminants. This will lead to increased light penetration and accumulation of 726 contaminants in the sediments which could create or exacerbate existing water quality

727 concerns, such as the eutrophication and hypoxia associated with excessive effluent728 retention [45].

729 Water column stratification is likely to be altered within the lagoon, affecting 730 seawater temperature; this will influence seasonal biological processes (e.g. 731 phytoplankton growth). This could lead to an increase in phytoplankton blooms, 732 which can be harmful to both marine biota and humans, causing a range of deleterious 733 physiological and environmental effects [131]. Certain harmful algae (HA; e.g. 734 Dinophysis) produce potent natural toxins that are concentrated by filter feeders and 735 passed through the food chain causing adverse affects on a variety of marine 736 organisms, and shellfish poisoning if consumed by humans [132,133]. Other HA are 737 non-toxic but attain high biomass levels which reduces the biodiversity of the 738 phytoplankton community structure and the amount of light reaching the benthos, 739 limiting the growth of photosynthetic species and the hunting activities of piscivorous 740 species [131,134–136]. The decomposition of blooms can lead to reductions in 741 dissolved oxygen concentrations which in turn will effect the biodiversity of the area 742 [137].

743

744 5.3 Research priorities

745 There is a need to utilise a multidisciplinary approach in assessing potential 746 contaminant issues, including hydrodynamic and sediment transport modelling to 747 enable a greater understanding of the fate of contaminants, thereby increasing 748 certainty surrounding the magnitude of impacts contaminants may cause. Conducting 749 robust baseline studies to distinguish between current and future impacts as part of 750 any research design is imperative. More detailed research investigating the toxic 751 properties of the chemicals used to maintain the devices and the long-term effects of 752 these to marine species should be carried out. This should be carried out concurrently 753 with further development of non-toxic alternative materials. In the case of tidal 754 lagoons, research needs to be undertaken to better understand the effects of enclosing 755 contaminants within an embayment. There is a need to model contaminant fluxes 756 under different scenarios when the lagoon is in place and calculate how much flushing 757 will occur through the turbines to enable the industry to understand the environmental 758 consequences of impounding the coastline. This research should include different 759 scenarios (e.g. flood events, storm surges), at different times of the year and at 760 different states of the tide to fully understand contaminant levels within a range of 761 environmental conditions. Finally, research is needed to develop the potential to

762 mitigate water quality issues: by identifying the main contributing sources and the

763 transport mechanisms work can be undertaken to find and test appropriate

764 bioremediators in these environments.

- 765

766 6. Socio-economic impacts and research priorities

767

768 A significant knowledge gap in the development of offshore wave and tidal 769 installations is the paucity of rigorous social science research to provide an evidence 770 base about the perceptions, attitudes and opinions of local communities at both an 771 individual and community levels, and at local, regional and national spatial scales. 772 Much of the social science surrounding renewable energy installations conducted to 773 date has focussed on wind power, since these technologies are at a more advanced 774 stage of development than wave or tide. Whilst it is likely that there will be some 775 similarities between attitudes towards wind farms and wave and tidal electricity 776 generation, as yet this assumption is unproven. The importance of fully 777 understanding the social attitudes surrounding renewable energy installations is vital 778 if negative public attitudes toward such developments are to be avoided.

779

780 Public attitudes towards electricity generation are complex and made up of 781 interrelated trade-offs that change across both place and time [138], and are 782 influenced by a person's underlying values and beliefs [139]. Energy installations 783 have a long history of being affected by changing public attitudes; the visual and 784 auditory disturbances as a result of wind power installations have been found to affect 785 individual's quality of life [140], and the impact on the landscape has led to 786 organisations such as Scottish National Heritage issuing guidance on siting wind 787 farms [141]. The effects of public opinion on energy industries can be catastrophic, 788 for example Japan has curtailed its nuclear program and is now exploring alternative 789 energy options as a result of wide-spread public mistrust in nuclear energy following 790 the Fukoshima disaster [142]. It is clear that public opinion is intrinsic to the 791 successful deployment of large-scale energy developments and without a thorough 792 understanding of the likely social and economic impact upon communities in close 793 proximity to potential wave and tidal installations, it is impossible to develop 794 strategies to ensure public acceptability. The economic incentives for developers to 795 progress technical capabilities in this arena will be curtailed should public opinion be

misunderstood or poorly accounted for; conversely, direct consumer benefits (for

example through reduced energy bills) is unlikely and must be made clear.

798

799 Economic benefits are often used to encourage the development of renewable 800 energies and this has certainly been the case in the development of wave and tidal 801 resources in the UK. At the country scale, Wales will benefit from developing its 802 wave and tidal resource, but whether benefits will filter down to the regional and local 803 scale will depend on local and regional abilities to provide the goods and services that 804 developers require. Fanning et al. [143] estimate that during the development and 805 installation phase, total expenditure leakage outside of Wales would be 35% for tidal 806 and 50% for wave. However, regional opportunities from installation and 807 maintenance aspects of marine renewable energy development do exist, with 808 employment estimates of between 35.3 and 22.9 full-time equivalent jobs (FTE) per 809 MW for tidal energy developments, and between 32.3 and 26.4 FTE per MW for 810 wave developments [143].

811

812 Such employment and economic opportunities do depend on appropriate 813 strategic plans being in place, for example to offer qualifications that allow 814 employment opportunities to be taken up by communities local to the development. 815 Equally, employment opportunities during the construction phase are not permanent 816 jobs; inevitably the labour force retracts when the installations are operational and 817 employees may be forced to re-locate from site to site. Furthermore, the development of Wales's marine energy resources may conflict with existing Welsh economic 818 819 activities, for example fisheries and tourism. Overall, the marine environment of 820 Wales is reported to produce an income of £6.8 billion and generate £2.5 billion in 821 GDP [144], whilst the fisheries sector within Wales has been valued at £105.4 million 822 and estimated to provide 1,659 FTE jobs [145]. An effective and scientifically robust 823 strategic overview of marine spatial planning in Wales is necessary to ensure that 824 conflicts between different uses of the marine environment are minimised, and 825 equitably divided where conflicts are unavoidable. These considerations are timely, as 826 the Welsh National Marine Plan being prepared by the Welsh Government is 827 currently in draft stage, and the need for widespread consultation within this process 828 has been recognised [146].

830 Clearly, the social and economic drivers behind marine renewable 831 developments are linked; care must be taken that both are considered in a strategic 832 evaluation of how Wales chooses to develop its marine resource. Initial findings from 833 research undertaken by the SEACAMS project indicates key knowledge gaps that 834 should be addressed in relation to the development of wave and tidal energies from a 835 social science perspective. Firstly, to understand how wave and tidal energy 836 developments are likely to impact levels of place attachment (i.e. the emotional or 837 affective bond between people and valued places). Aquatic environment are valued 838 environments [147], and despite the perception that wind and tidal devices are 839 predominantly below sea level and therefore 'invisible', there are associated on-shore 840 infrastructure needed, for example connections to the National Grid. Although MREIs 841 can provide important recreational opportunities, they also have the potential to 842 disrupt local communities sense of what is unique about their landscape [148]. Whilst 843 the benefits of developments are often focussed on employment opportunities, 844 research has shown that communities can be sceptical about whether local people 845 have the skills needed; moreover, in communities with strong place attachment, the 846 promise of employment is not enough to override concerns relating to the visual 847 impact any development would have on the landscape [148]. Additionally, no-take 848 zones or exclusion zones in areas where fisheries play a key role in the local economy 849 are likely to prove contentious and may limit the wide-scale roll out of MREIs [149]. 850

851 Conversely, in communities where renewable energy developments result in 852 direct community benefits, for example through reduced energy prices or land rental 853 revenue, acceptability has been shown to be higher [150–152], but little research has 854 documented the limits of this relationship, or expanded this to cover the role of wave 855 and tidal energy development. Other potential benefits, such as coastal and flood 856 protection (in the case of tidal lagoons), the provision of amenity opportunities, or the 857 creation of additional marine habitats may positively influence local communities. 858 Finally, the role of trust, faith and fairness in both the development process and the 859 siting process have been shown to influence acceptability of renewable energy 860 developments [153–155]. Determining how these factors relate to wave and tidal 861 energy developments will allow more effective public engagement opportunities, 862 potentially reduce conflict, and lead to realistic expectations for both local 863 communities and developers.

864

865

866 **7. Conclusions**

867

868 The marine renewable energy industry is at a critical stage of development 869 in Wales, as the wave and tidal demonstration zones begin to fulfill their role as 870 device testing locations, and some developments move from the tests device to the 871 small array stage. The research challenges presented are common to those facing 872 many countries with the potential for the implementation of several marine renewable 873 energy technologies (Table 1). Determination of the optimum siting for devices in 874 relation to the resource is a priority for developers, whilst, at broader spatial scales, 875 physical and ecological impacts and the relationships with grid connections are 876 important policy and consenting considerations. In addition, societal attitudes towards 877 marine renewable energy will continue to evolve as developments progress and social 878 and economic impacts become clearer.

Appropriate design and management measures will maximize positive
influences of MREIs on local biodiversity and the marine environment. For instance,
as the designation of additional marine protected areas is planned for Wales,
consideration should be given to the potential for both conflict and synergy between
MPAs and MREIs.

Ongoing research will reduce uncertainty in the estimation of impacts from
MREIs, and assist in reducing the risks to developers. There is currently an
opportunity to collect baseline data within appropriately designed studies to facilitate
assessment of impacts following device installation at Welsh Demonstration Zones.
However, prior to installation, a combination of modeling studies and conducting
research on existing artificial structures in the marine environment offers the best
potential to predict the effects of MREIs.

894 Figure Captions:

895

Figure 1. Locations of marine renewable energy development and test sites around
Wales: a) tidal stream sites, including the West Anglesey Tidal Demonstration Zone,
b) tidal lagoon sites, c) wave power sites, including the South Pembrokeshire Wave

899 Demonstration Zone, d) main electricity grid connections around the coastline of

900 Wales.

901

902 Figure 2. Sites of environmental conservation importance around the Welsh coastline:

a) protected area which are primarily land-based, but which extend into the coastal

904 environment, b) protected areas with a marine focus, c) indicative boundaries of

- newly proposed marine protected areas which are under consideration.
- 906

907 Figure 3. The tidal energy resource of the Irish Sea. Tidal range resource is shown in

908 panel (a), as the mean spring tide amplitude in metres with lines of co-phase in hours,

relative to the port of Holyhead (red circle of panel a). The tidal-stream resource is

shown in panel (b), as the major axis of peak spring tidal ellipse (M2 and S2 in m/s)

911 with lines of co-phase in hours relative to the Anglesey tidal-stream energy

912 demonstration zone (red circle of panel b). Both the tidal range and tidal-stream

913 energy resource maps (a and b respectively) are calculated using hourly data from the

- 914 well validated high-resolution 3D ROMS tidal model of [5].
- 915

Figure 4. Simulated annual mean (2014) wave power in the Irish Sea, based on the

917 SWAN wave model and ERA-Interim wind fields. The model is nested within an

918 outer SWAN model of the North Atlantic [33].

919

Table 1. Summary of research challenges within Welsh Marine Renewable EnergyDevelopments.

922

923

924 Acknowledgements:

This project has been part funded by the European Regional Development Fund

through the Welsh Government's Sustainable Expansion of the Applied Coastal and

927 Marine Sectors (SEACAMS) project. M. Lewis is funded by the Sêr Cymru National

928 Research Network for Low Carbon, Energy and the Environment (NRN-LCEE)

through the QUOTIENT project. The authors would like to acknowledge the input

930 from the reviewers of this manuscript.

Table

Research Challenge	Importance/Priority level	Existing level of knowledge	Present research level
Cumulative regional scale impacts of multiple marine renewable energy device arrays	Medium	Low	Low
Effects of scaling up from individual test devices to commercial arrays	High	Low	Low
Fine-scale functional use, foraging and diving behaviour at MREI sites by top predators	High	Low	Medium
Interactions between MREIs and coastal/offshore sediment transport, deposition and erosion patterns	Medium	Medium	Medium
Active monitoring during device operation and assessment of marine mammal behavioural response	High	Low	Medium
Socio-economic impacts and public perceptions of MREIs	High	Low	Low
Biological and chemical contaminant impacts and associated transport pathways	Medium	Low	Low
Localised habitat alterations and ecosystem impacts of novel habitat provision	Medium	Medium	High
Implications for marine invasive species survival, reproduction and range expansion	Medium	Low	High
Alterations of turbidity, light attenuation, and primary productivity affecting biogeochemical cycling	Low	Low	Low
