## Abstract

Mineral authigenesis from their dissolved sea salt matrix is an emergent feature of sea ice brines, fuelled by dramatic equilibrium solubility changes in the large sub-zero temperature range of this cryospheric system on the surface of high latitude oceans. The multi-electrolyte composition of seawater results in the potential for several minerals to precipitate in sea ice, each affecting the in-situ geochemical properties of the sea ice brine system, the habitat of sympagic biota. The solubility of two of these minerals, gypsum ( $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$ ) and hydrohalite ( $\text{NaCl} \cdot 2\text{H}_2\text{O}$ ), was investigated in high ionic strength multi-electrolyte solutions at below-zero temperatures to examine their dissolution–precipitation dynamics in the sea ice brine system. The gypsum dynamics in sea ice were found to be highly dependent on the solubilities of mirabilite and hydrohalite between 0.2 and  $-25.0$  °C. The hydrohalite solubility between  $-14.3$  and  $-25.0$  °C exhibits a sharp change between undersaturated and supersaturated conditions, and, thus, distinct temperature fields of precipitation and dissolution in sea ice, with saturation occurring at  $-22.9$  °C. The sharp changes in hydrohalite solubility at temperatures  $\leq -22.9$  °C result from the formation of an ice–hydrohalite aggregate, which alters the structural properties of brine inclusions in cold sea ice. Favourable conditions for gypsum precipitation in sea ice were determined to occur in the region of hydrohalite precipitation below  $-22.9$  °C and in conditions of

metastable mirabilite supersaturation above  $-22.9\text{ }^{\circ}\text{C}$  (investigated at  $-7.1$  and  $-8.2\text{ }^{\circ}\text{C}$  here) but gypsum is unlikely to persist once mirabilite forms at these warmer ( $> -22.9\text{ }^{\circ}\text{C}$ ) temperatures. The dynamics of hydrohalite in sea ice brines based on its experimental solubility were consistent with that derived from thermodynamic modelling (FREZCHEM code) but the gypsum dynamics derived from the code were inconsistent with that indicated by its experimental solubility in this system. Incorporation of hydrohalite solubility into a 1D thermodynamic model of the growth of first-year Arctic sea ice showed its precipitation to initiate once the incoming shortwave radiation dropped to  $0\text{ W m}^{-2}$ , and that it can reach concentrations of  $9.9\text{ g kg}^{-1}$  within the upper and coldest layers of the ice pack. This suggests a limited effect of hydrohalite on the albedo of sea ice. The insights provided by the solubility measurements into the behaviour of gypsum and hydrohalite in the ice–brine system cannot be gleaned from field investigations at present.

## 1. Introduction

When sea ice forms in high latitude environments, seawater solutes are expelled from the ice crystal matrix and a concentrated brine forms which becomes trapped as inclusions in the sea ice microstructure (Petrich and Eicken, 2010). At ice–brine equilibrium, the brine inclusions have a temperature-dependent size and composition with respect to major seawater ions, the latter further governed by the solubility of their related salts (Marion, 2001). The Na–K–Mg–Ca– $\text{SO}_4$ –Cl– $\text{H}_2\text{O}$  system contains 99.4 % of the total dissolved ions in Standard Seawater by mass (Millero et al., 2008), and, as sea ice temperature changes, solid–solution reactions of the brine with the predominantly hydrated salts of these major ions dominate the geochemistry of the system (Gitterman, 1937; Nelson and Thompson, 1954). The combined effect of changing temperature, solute concentration, and mineral (sea salt) solubility in the sea ice brine is that, as sea ice cools, the brines become

15 sequentially supersaturated with respect to a suite of minerals. Each min-  
 16 eral in the sequence has a distinct solubility–temperature relationship and,  
 17 hence, a distinct equilibrium onset temperature of precipitation from the  
 18 brines between the freezing point of seawater and its eutectic (Gitterman,  
 19 1937; Nelson and Thompson, 1954; Marion et al., 1999). These authigenic  
 20 minerals become part of the heterogeneous sea ice matrix (Light et al., 2003;  
 21 Dieckmann et al., 2008; Geilfus et al., 2013), contributing to its optical, me-  
 22 chanical, thermal, and structural properties (Assur, 1960; Light et al., 2004;  
 23 Carns et al., 2015). Precipitation of sea ice minerals also modifies the physico-  
 24 chemical properties of the brine inclusions, including salinity (Butler et al.,  
 25 2016a) and the inter-ionic ratios of dissolved constituents, thus contributing  
 26 to the physiological challenges for ice-associated micro-organisms (Thomas  
 27 and Dieckmann, 2002). Further, mineral precipitation features in the salt  
 28 mass balance of saline cryogenic systems in past and present polar environ-  
 29 ments on Earth (Assur, 1960; Light et al., 2009) and other water-bearing  
 30 planetary bodies (Marion and Kargel, 2008).

31 In absence of metastable supersaturated conditions (see section 2.3), the  
 32 suite of minerals that can precipitate within sea ice includes ikaite ( $\text{CaCO}_3 \cdot$   
 33  $6\text{H}_2\text{O}$ ), mirabilite ( $\text{Na}_2\text{SO}_4 \cdot 10\text{H}_2\text{O}$ ), hydrohalite ( $\text{NaCl} \cdot 2\text{H}_2\text{O}$ ), gypsum ( $\text{CaSO}_4 \cdot$   
 34  $2\text{H}_2\text{O}$ ), sylvite ( $\text{KCl}$ ),  $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ , and antarcticite ( $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ ) at  
 35 progressively decreasing temperatures. Depending on the exact sequence of  
 36 mineral precipitates, the eutectic temperature of sea ice can be  $-36^\circ\text{C}$  (in  
 37 association with  $\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ ; Gitterman, 1937) or  $-54^\circ\text{C}$  (in association  
 38 with antarcticite; Nelson and Thompson, 1954).

39 Ikaite has been identified in natural and experimental sea ice (Dieckmann  
 40 et al., 2008; Geilfus et al., 2013; Fischer et al., 2013). The solubility of ikaite  
 41 in sea ice brines has been investigated to  $-7.5^\circ\text{C}$ , and this  $\text{CaCO}_3$  polymorph  
 42 can precipitate below  $-2^\circ\text{C}$  depending on the brine  $p\text{CO}_2$  (Papadimitriou  
 43 et al., 2013). Mirabilite solubility in sea ice brines has been investigated  
 44 to  $-20.6^\circ\text{C}$  (Butler et al., 2016b). Sea ice brines become supersaturated

45 with respect to mirabilite at temperatures  $\leq -6.4$  °C, and its consequent  
 46 precipitation causes this mineral to become the main sink of  $\text{SO}_4^{2-}$  in sea ice  
 47 brines (Marion et al., 1999; Butler et al., 2016b). Gypsum has long been  
 48 predicted to precipitate from frozen seawater but information on its stabil-  
 49 ity in sea ice brines is less precise than for ikaite and mirabilite. From the  
 50 major ion composition of residual brine during the freezing of synthetic sea-  
 51 water to its eutectic, Gitterman (1937) inferred that gypsum precipitation  
 52 should occur at temperatures below  $-15$  °C. In these experiments, all po-  
 53 tential authigenic minerals were allowed to interact with the residual brine  
 54 to solid-solution equilibrium. More recently, Marion et al. (1999) combined  
 55 thermodynamic model predictions (FREZCHEM) with experimental analy-  
 56 sis of seawater brines seeded with gypsum at  $-15$ ,  $-20$  and  $-26$  °C, and  
 57 proposed that gypsum in brines becomes supersaturated at  $-22.2$  °C but  
 58 its precipitation is enhanced below  $-22.9$  °C as a result of brine-mirabilite-  
 59 hydrohalite interaction. Specifically, initial removal of  $\text{Na}^+$  and  $\text{SO}_4^{2-}$  from  
 60 the brine via mirabilite precipitation between  $-6.4$  and  $-22.9$  °C is followed  
 61 by additional removal of  $\text{Na}^+$  from the brine through hydrohalite precipita-  
 62 tion upon further cooling. The large  $\text{Na}^+$  change via hydrohalite precipitation  
 63 results in brine undersaturation with respect to mirabilite, which dissolves  
 64 when in contact with the brine. The liberated  $\text{SO}_4^{2-}$  from mirabilite disso-  
 65 lution enhances the degree of gypsum supersaturation of the brine, resulting  
 66 in enhanced gypsum precipitation (Gitterman, 1937; Marion et al., 1999).  
 67 In contrast, the effects of gypsum precipitation on brine composition during  
 68 seawater freezing were not observed by Nelson and Thompson (1954) due to  
 69 their experimental protocol, in which the minerals were removed from the  
 70 natural seawater-derived brine as they formed. The sea ice brine systems rep-  
 71 resented by the experimental protocols of Gitterman (1937) and Nelson and  
 72 Thompson (1954) are considered to be representative of the equilibrium crys-  
 73 tallisation (hereafter full crystallisation) pathway and the fractional crystalli-  
 74 sation pathway, respectively (Marion et al., 1999; Marion and Kargel, 2008;

75 Butler and Kennedy, 2015). In an experimental approach representative of  
76 the full crystallisation pathway, the brine–mirabilite–hydrohalite interaction  
77 was observed during cooling and warming of frozen seawater brines but gyp-  
78 sum was not identified Butler and Kennedy (2015).

79 Gypsum has recently been identified in experimental and natural sea ice  
80 at temperatures between  $-2$  and  $-10$  °C, and, in view of this, has been  
81 proposed as a potential marine deposit in polar seas (Geilfus et al., 2013).  
82 This suggests more complex gypsum dynamics in the sea ice system than  
83 construed from the available information about the sub-zero temperature  
84 field of gypsum stability in seawater brines outlined above. This issue can  
85 be elucidated from a more detailed knowledge of the equilibrium gypsum  
86 solubility in sea ice conditions.

87 Here, we investigated the characteristics of the gypsum–brine reaction in  
88 sea ice via measurements of the concentration-based (stoichiometric) solubil-  
89 ity of this mineral in relevant brines at below-zero temperatures. We sought  
90 to identify the conditions that can lead to internal gypsum authigenesis and  
91 stability in the large below-zero temperature and salinity ranges of sea ice  
92 brines. Knowledge of the hydrohalite dynamics in the sea ice system is es-  
93 sential for this purpose given the common ion effect on mineral stability of  
94 the brine–gypsum–mirabilite–hydrohalite interaction outlined earlier and the  
95 available information about mirabilite solubility in the sea ice system in our  
96 previous work (Butler et al., 2016b). Thermodynamic modelling (Marion  
97 et al., 1999) and experimental observations from the Gitterman (1937) and  
98 Nelson and Thompson (1954) experiments predict that hydrohalite precipi-  
99 tates in sea ice below  $-22.9$  °C. Its presence has been identified in laboratory  
100 experiments on frozen seawater brines (Butler and Kennedy, 2015) and in  
101 sea ice (Light et al., 2003), and affects the optical, mechanical, and frictional  
102 properties of sea ice (Light et al., 2004; Carns et al., 2015). From the onset,  
103 hydrohalite precipitation is rapid and by  $-30$  °C, 87 % of dissolved NaCl is  
104 removed from the brine as a result (Richardson, 1976). In frozen seawater

105 from a starting absolute salinity of  $35 \text{ g kg}_{\text{solution}}^{-1}$  (in the absence of brine  
 106 drainage), hydrohalite concentrations can approach 4 % by mass by  $-40 \text{ }^{\circ}\text{C}$   
 107 (Richardson, 1976; Light et al., 2003). Precipitation of hydrohalite has been  
 108 shown to be closely associated with enhanced ice formation, which substan-  
 109 tially reduces the volume of brine remaining in the ice (Richardson, 1976;  
 110 Butler and Kennedy, 2015).

111 The current investigation expands upon recent work on mirabilite solu-  
 112 bility in similar conditions (Butler et al., 2016b). The solubility of both gyp-  
 113 sum and hydrohalite was measured to a minimum temperature of  $-25.0 \text{ }^{\circ}\text{C}$ .  
 114 Because of the large increase in hydrohalite solubility with increasing tem-  
 115 perature, the maximum experimental temperature was  $-14.3 \text{ }^{\circ}\text{C}$  while that  
 116 for gypsum solubility was  $0.2 \text{ }^{\circ}\text{C}$ , with experiments designed to investigate  
 117 the behaviour of gypsum under conditions equivalent to fractional and full  
 118 crystallisation pathways. Finally, given the dominance of hydrohalite as a  
 119 mineral precipitate in cold sea ice, its solubility data set was incorporated  
 120 into a 1D model of the growth of snow-free first-year sea ice to allow eval-  
 121 uation of its depth distribution and temporal dynamics. The dynamics of  
 122 gypsum are shown here to be too complex in its dependence on mirabilite  
 123 and hydrohalite dynamics for this modelling approach.

## 124 2. Methods

### 125 2.1. Synthetic mineral preparation and synchrotron X-ray powder diffraction

126 Synthetic gypsum, hydrohalite, and mirabilite were used for seeding the  
 127 solid–solution equilibrium reaction and were prepared based on the methods  
 128 described in Wang et al. (2012), Light et al. (2009), and Butler et al. (2016b),  
 129 respectively. All synthetic solids were stored in screw-capped bottles; gypsum  
 130 was stored at room temperature, while hydrohalite and mirabilite were stored  
 131 at  $-20 \text{ }^{\circ}\text{C}$ .

132 The mineralogy of the synthetic solids and of some of the mineral aggre-  
 133 gates recovered following solid–solution reaction was characterised at  $-30 \text{ }^{\circ}\text{C}$

134 using synchrotron X-ray powder diffraction (XRPD) on Beamline I11 at  
 135 Diamond Light Source (Harwell Science and Innovation Campus, Oxford-  
 136 shire, UK). Published cell parameters for hydrohalite (Klewe and Pederson,  
 137 1974), gypsum (Boeyens and Ichharam, 2002), and mirabilite (Brand et al.,  
 138 2009) were used as an initial starting point for LeBail (Le Bail et al., 1988)  
 139 and Rietveld (Rietveld, 1969) refinements in TOPAS-Academic V6 software  
 140 (Coelho, 2012). Based on the semi-quantitative (Hillier, 2003) Rietveld re-  
 141 finements, it was established that all batches of synthetic mineral seeds dis-  
 142 played  $\geq 99$  % purity.

## 143 *2.2. Closed bottle incubations and brine analysis*

144 Mineral solubility was determined with closed bottle incubations of nat-  
 145 ural or synthetic seawater and brines with synthetic solids to solid–solution  
 146 equilibrium as previously used for this purpose (Mucci, 1983; Papadimitriou  
 147 et al., 2013; Butler et al., 2016b). The time to solid–solution equilibrium  
 148 was determined by monitoring the change in  $\text{Ca}^{2+}$  with time for gypsum  
 149 and in  $\text{Cl}^-$  for hydrohalite during incubation (protocols described in sec-  
 150 tion 2.4). Changes sustained within the analytical uncertainty over 1 week  
 151 were taken to indicate attainment of solid–solution equilibrium. Using this  
 152 approach the gypsum experiments were incubated for between 41 and 90  
 153 days, and hydrohalite experiments incubated for between 24 and 36 days.  
 154 All incubation experiments were conducted in triplicate, with bottles fully  
 155 submersed in constant temperature circulating chillers and shaken by hand  
 156 daily to facilitate exposure of the mineral seed to the bulk solution. Incu-  
 157 bation temperatures were controlled by Grant RC 1400G recirculating baths  
 158 and Grant TX120/TX150 circulators coupled with Grant R2/R3 refrigera-  
 159 tion units. Chiller temperatures were monitored at thirty-minute intervals  
 160 using data loggers (Tinytag aquatic 2 TG4100).

161 Detailed preparation protocols for the natural and synthetic seawater  
 162 brines can be found in Butler et al. (2016b). The synthetic seawater and  
 163 brines were prepared with their major ionic composition ( $\text{NaCl}$ ,  $\text{Na}_2\text{SO}_4$ ,

164  $\text{CaCl}_2$ ,  $\text{MgCl}_2$ ,  $\text{KCl}$ ) a linear function of salinity relative to the recipe of  
 165 salinity 35 synthetic seawater in Papadimitriou et al. (2016). Natural brines  
 166 were prepared from local seawater (Menai Strait, 53.1806°N, 4.2333°W) by  
 167 freezing. The major ion composition (as total ion concentrations) of natural  
 168 and synthetic experimental solutions was fully quantified before incubation  
 169 to determine their initial saturation state with respect to the investigated  
 170 minerals, and after incubation for the determination of the relevant mineral  
 171 solubility.

172 The major ion composition of the samples was determined within 4 weeks  
 173 from sampling, with refrigerated storage before analysis. To eliminate the  
 174 risk of mineral precipitation during storage, all samples were immediately  
 175 diluted gravimetrically to a practical salinity of 35 with deionised water.  
 176 The  $\text{Na}^+$  and  $\text{K}^+$  concentrations were determined by ion chromatography  
 177 on a Dionex Ion Exchange Chromatograph ICS 2100. The  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$   
 178 concentrations were determined by potentiometric titration as described by  
 179 Papadimitriou et al. (2013). The  $\text{Cl}^-$  concentration was determined by gravi-  
 180 metric Mohr titration with 0.3 M  $\text{AgNO}_3$  standardised against  $\text{NaCl}$  purified  
 181 by recrystallisation. The  $\text{SO}_4^{2-}$  concentration was determined by precipita-  
 182 tion as  $\text{BaSO}_4$  in ethylenediaminetetraacetic acid (EDTA) followed by gravi-  
 183 metric titration with  $\text{MgCl}_2$  (Howarth, 1978). Repeat measurements of the  
 184 major ion composition of local seawater were used as an internal standard  
 185 relative to the composition of Standard Seawater (Millero et al., 2008). This  
 186 comparison provided an estimate of measurement accuracy and precision rel-  
 187 ative to Standard Seawater, summarised in Table 1.

### 188 2.3. Determination of saturation state and stoichiometric solubility products

189 Mineral solubility is defined here as the equilibrium concentration-based  
 190 (stoichiometric) solubility product at mineral–solution equilibrium,  $K_{\text{sp,gypsum}}^* =$   
 191  $[\text{Ca}^{2+}]_{\text{eqm}}[\text{SO}_4^{2-}]_{\text{eqm}}$  and  $K_{\text{sp,hydrohalite}}^* = [\text{Na}^+]_{\text{eqm}}[\text{Cl}^-]_{\text{eqm}}$ , with brackets de-  
 192 noting total ion concentrations and ‘eqm’ subscripts denoting equilibrium  
 193 conditions. The  $K_{\text{sp}}^*$  is a function of temperature, ionic strength (salinity),

Table 1: The accuracy and precision of brine analyses estimated using repeat measurements of local seawater (normalised to practical salinity = 35) as an internal standard relative to the composition of Standard Seawater (Millero et al., 2008).

	Standard Seawater	Measurements $\pm \sigma$	$\Delta \pm \sigma$
		mmol kg <sub>sol</sub> <sup>-1</sup>	%
Na <sup>+</sup>	468.97	470.53 $\pm$ 7.97 ( $n = 29$ )	0.33 $\pm$ 1.70
K <sup>+</sup>	10.21	10.11 $\pm$ 0.05 ( $n = 9$ )	-0.97 $\pm$ 0.49
Mg <sup>2+</sup>	52.82	52.63 $\pm$ 0.54 ( $n = 82$ )	-0.36 $\pm$ 1.02
Ca <sup>2+</sup>	10.28	10.24 $\pm$ 0.14 ( $n = 82$ )	-0.39 $\pm$ 1.36
Cl <sup>-</sup>	545.87	548.48 $\pm$ 6.90 ( $n = 38$ )	0.48 $\pm$ 1.26
SO <sub>4</sub> <sup>2-</sup>	28.24	28.34 $\pm$ 0.41 ( $n = 35$ )	0.35 $\pm$ 1.45

194 and solution composition (Papadimitriou et al., 2013; Butler et al., 2016b),  
195 and is hereafter reported as the negative common logarithm ( $pK_{\text{sp}}^*$ ) on the  
196 per kg<sub>solution</sub> basis of the concentration measurements. The  $pK_{\text{sp}}^*$  values of  
197 each mineral were fitted to non-linear functions of temperature ( $T$ , in K;  
198 eq. 1), using Regression in the Data Analysis ToolPak of Microsoft Excel,  
199 with the fitted regression coefficients A to D given in Table 2.

$$pK_{\text{sp}}^*(T) = A + BT + CT^2 + DT^3, \quad (1)$$

200 The saturation state of samples was determined as  $\Omega = \text{ICP}/K_{\text{sp}}^*$  (Berner,  
201 1980), with ICP = total ion concentration product prior to seeding (i.e.  
202  $[\text{Ca}^{2+}][\text{SO}_4^{2-}]$  for gypsum, and  $[\text{Na}^+][\text{Cl}^-]$  for hydrohalite) and  $K_{\text{sp}}^*$  as above.  
203 When  $\Omega < 1$  the initial solution is undersaturated with respect to the min-  
204 eral. When  $\Omega > 1$  the initial solution is supersaturated with respect to the  
205 mineral. Supersaturation is a metastable state that results in mineral pre-  
206 cipitation if suitable nucleation sites are provided. The  $\Omega$  values were fitted  
207 to non-linear functions of temperature ( $T$ , in K; eq. 1), with fitted regression  
208 coefficients also given in Table 2. Each solid-solution equilibrium system  
209 was defined by the solid phases (including ice, if present) in contact with the  
210 brine at equilibrium. For example, a brine attaining equilibrium in contact

211 with mirabilite and gypsum will be defined as a brine–mirabilite–gypsum  
212 equilibrium system.

213 The solubility of gypsum was determined in both natural and synthetic  
214 brines between 0.2 and  $-5.0$  °C to investigate potential matrix effects on the  
215  $K_{\text{sp,gypsum}}^*$ . The differences between  $pK_{\text{sp,gypsum}}^*$  in natural and synthetic brine  
216 experiments over this temperature range were generally within the analytical  
217 uncertainty (Figure 1; Table 3) and, therefore, only synthetic brines were  
218 used at temperatures below  $-5.0$  °C. Given the dominance of  $\text{Na}^+$  and  $\text{Cl}^-$   
219 in the composition of seawater and their tendency to remain as free ions in  
220 solution (Millero et al., 2008; Marion and Kargel, 2008), the determination of  
221  $K_{\text{sp,hydrohalite}}^*$  only in synthetic brines, as done here, was considered to provide  
222 values representative of those in natural seawater-derived brines.

#### 223 2.4. Incubation protocols

224 Due to the large investigated temperature range and the sequential pre-  
225 cipitation of minerals from the brine at various points in this range, three  
226 different protocols were employed for the bottle incubations.

227 *Protocol-1: Gypsum solubility.* Between 0 and  $-6$  °C, major ions in  
228 seawater and its brines during freezing (absolute salinity,  $S_A = 35$  to 100 g  
229  $\text{kg}_{\text{solution}}^{-1}$ ; hereafter,  $\text{g kg}^{-1}$ ) behave conservatively, and so, synthetic solutions  
230 were prepared at room temperature with Standard Seawater major ionic ra-  
231 tios and composition (Millero et al., 2008) and were seeded with gypsum.  
232 Solutions of  $S_A \geq 35$   $\text{g kg}^{-1}$  were incubated within 0.3 °C of their freez-  
233 ing point, which was estimated using the equation from Millero and Leung  
234 (1976).

235 *Protocol-2: Gypsum and hydrohalite solubilities.* Protocol-2 was used for  
236 incubations between  $-6$  and  $-22$  °C to take into account the ice–brine–  
237 mirabilite reaction, which is documented in this temperature range (Butler  
238 et al., 2016b). Conservative seawater brines were prepared ( $S_A = 75$  to 225  
239  $\text{g kg}^{-1}$ ), cooled to at least 2 °C colder than their freezing point, and were  
240 incubated with mirabilite seed until attainment of ice–brine–mirabilite equi-

Table 2: Coefficients for use with equation 1 describing the change in  $pK_{sp}^*$  and  $\Omega$  for gypsum and hydrohalite, and the mass of hydrohalite to precipitate from frozen seawater ( $S_A = 35 \text{ g kg}^{-1}$ ), all as functions of temperature (K).

<sup>a</sup> Extrapolated to  $-22.8 \text{ }^{\circ}\text{C}$  in figures 1 and 2

241 librium. The brine was then extracted by in-situ filtration using WHATMAN  
 242 0.2  $\mu\text{m}$  syringe filters in line with Teflon tubing extensions. The filtrate was  
 243 transferred to triplicate 25 ml bottles and was returned to the circulating  
 244 chiller seeded with either gypsum or hydrohalite until equilibrium had been  
 245 attained. It is worth emphasising that hydrohalite and ice cannot co-exist  
 246 above  $-22.9\text{ }^{\circ}\text{C}$  (Marion et al., 1999; Marion and Kargel, 2008), therefore  
 247 all hydrohalite solubility experiments carried out using protocol-2 represent  
 248 the extent to which hydrohalite would dissolve (i.e. the degree of undersat-  
 249 uration) in the solutions extracted from an ice–brine–mirabilite equilibrium  
 250 system.

251 *Protocol-3: Gypsum and Hydrohalite solubilities.* Protocol-3 was followed  
 252 at the coldest experimental temperatures ( $-23.7$  and  $-25.0\text{ }^{\circ}\text{C}$ ) to circum-  
 253 vent the substantial reduction in brine volume following hydrohalite precipi-  
 254 tation. Conservative seawater brines were prepared to  $S_A \sim 225\text{ g kg}^{-1}$  in 500  
 255 ml bottles and were cooled to  $-21\text{ }^{\circ}\text{C}$  when mirabilite seed was added, with  
 256 ice formation and mirabilite precipitation ensuing. At this stage, the exper-  
 257 imental medium included an ice layer at the brine surface and a mirabilite  
 258 layer at the bottom of the bottle. The ice–brine–mirabilite system was then  
 259 cooled to either  $-23.7$  or  $-25.0\text{ }^{\circ}\text{C}$ . On these occasions, buoyant, irregular,  
 260 mottled bright white crystal flocs formed during cooling to target tempera-  
 261 ture and filled the bottle at thermal equilibrium, consistent with reports of  
 262 ice–hydrohalite aggregates (Nelson and Thompson, 1954; Assur, 1960; Mc-  
 263 Carthy et al., 2007; Light et al., 2009). The residual brine was trapped  
 264 within the aggregate and was extracted by drainage into a hole bored into  
 265 the aggregate with a steel rod. The extracted brine was considered rep-  
 266 resentative of the fractional crystallisation pathway (section 1) because the  
 267 mirabilite precipitate at the bottom of the bottle was isolated from further re-  
 268 action with the emergent ice–hydrohalite aggregate and its interstitial brine  
 269 (previously at equilibrium with the mirabilite). The extracted brine pro-  
 270 vided the measurements for the determination of  $K_{\text{sp,hydrohalite}}^*$  at  $-23.7$  and

271  $-25.0\text{ }^{\circ}\text{C}$ , as well as aliquots for further incubations and the determination of  
 272 the  $K_{\text{sp,gypsum}}^*$  at these temperatures. To this end, the extracted brines were  
 273 incubated with gypsum seed with and without mirabilite seed. Gypsum sol-  
 274 ubility was therefore determined under two different conditions at  $-23.7$  and  
 275  $-25.0\text{ }^{\circ}\text{C}$ : (i) in the absence of mirabilite seed, representative of the fractional  
 276 crystallisation pathway of restricted brine–mirabilite interaction limited by  
 277 the ice–hydrohalite aggregate; and (ii) in the presence of mirabilite seed, rep-  
 278 resentative of the full crystallisation pathway of unrestricted brine–mirabilite  
 279 interaction.

280 *Additional protocol: Gypsum solubility.* Although seawater brines be-  
 281 come supersaturated with respect to mirabilite at  $T \leq -6.4\text{ }^{\circ}\text{C}$ , persistence  
 282 of metastable mirabilite supersaturation has been observed between  $-7$  and  
 283  $-8\text{ }^{\circ}\text{C}$  in the absence of mirabilite seed (Butler et al., 2016b). To examine  
 284 the potential for gypsum precipitation in this narrow temperature window of  
 285 metastable mirabilite supersaturation in sea ice brines, bottle incubations of  
 286 conservative solutions were undertaken at  $-7.1\text{ }^{\circ}\text{C}$  ( $S_A = 113.9\text{ g kg}^{-1}$ ) and  
 287  $-8.2\text{ }^{\circ}\text{C}$  ( $S_A = 125.1\text{ g kg}^{-1}$ ) in an adaptation of protocol-2 that omitted  
 288 the addition of mirabilite seed. At these temperatures, the solutions were  
 289 supersaturated with respect to mirabilite and their ionic composition repre-  
 290 sented that at ice–brine equilibrium. The solutions were seeded with gypsum,  
 291 the  $K_{\text{sp,gypsum}}^*$  was determined at brine–gypsum equilibrium, and mirabilite  
 292 seed was added to the incubations, resulting in mirabilite precipitation and  
 293 dissolution of the gypsum precipitate/seed, which remained in excess. The  
 294 system was then allowed to attain brine–mirabilite–gypsum equilibrium, i.e.,  
 295 the same system investigated using the original protocol-2, but with reversed  
 296 seeding, from which the  $K_{\text{sp,gypsum}}^*$  was again determined.

## 297 2.5. *FREZCHEM modelling of gypsum and hydrohalite solubilities*

298 As a means of relating the experimental  $K_{\text{sp,gypsum}}^*$  and  $K_{\text{sp,hydrohalite}}^*$  with  
 299 their thermodynamic counterparts at infinite dilution in pure water, their val-  
 300 ues were compared with those calculated from the thermodynamic database

Table 3: The absolute salinity ( $S_A$ ) of incubated brines prior to seeding with gypsum, incubation temperature at point of sampling,  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  concentrations at equilibrium, the resulting measured  $pK_{\text{sp,gypsum}}^*$  and  $\Omega_{\text{gypsum}}$ , and the  $\Delta\text{Ca}^{2+}$  observed over the course of each experiment included as a measure of reaction direction ( $\Delta\text{Ca}^{2+} = \text{Ca}_{\text{eqm}}^{2+} - \text{Ca}_{\text{initial}}^{2+}$ ). The  $S_A$  measured between 0.2 and  $-6.0$  °C are at ice–brine equilibrium, while those at  $-6.8$  °C and below were measured at ice–brine–mirabilite equilibrium. In each case, equilibrium was attained by gypsum dissolution, evidenced by positive  $\Delta\text{Ca}^{2+}$  values. Tabulated errors are calculated as the standard deviation of measurements from triplicate experiments.

of the FREZCHEM (version 15.1) with ice, mirabilite, gypsum, and hydro-  
halite the only solids enabled in the mineral database. The FREZCHEM code  
is frequently used to investigate geochemical reactions in the cryosphere. It is  
based on the Pitzer formalism of ionic interactions in concentrated electrolyte  
solutions and includes ion pairs ( $\text{CaCO}_3^0$ ,  $\text{MgCO}_3^0$ ,  $\text{MgOH}^+$ ) with high for-

306 mation constants (He and Morse, 1993), while it also accounts for the  $\text{SO}_4^{2-}$ –  
 307  $\text{HSO}_4^-$  equilibrium (Marion and Grant, 1994; Marion and Farren, 1999). The  
 308 code runs replicated the experimental starting solution compositions (i.e.  
 309 prior to seeding) studied in the protocols outlined in section 2.4. Because  
 310 the code is predominately designed to simulate mineral–solution equilib-  
 311 rium from precipitation, excess gypsum or hydrohalite were added to the  
 312 FREZCHEM input files when the brine–gypsum and brine–hydrohalite equi-  
 313 librium was simulated for undersaturated experimental brines. The deriva-  
 314 tion of  $K_{\text{sp,gypsum}}^*$  and  $K_{\text{sp,hydrohalite}}^*$  from the code output was based on that  
 315 used for ikaite (Papadimitriou et al., 2013) and mirabilite (Butler et al.,  
 316 2016b) solubilities in sea ice brines.

## 317 *2.6. First-year sea ice modelling*

318 The FREZCHEM code was also run to simulate freezing of Standard  
 319 Seawater (Millero et al., 2008) in order to determine the mass of hydrohalite  
 320 precipitate as a function of temperature between  $-22.9^\circ\text{C}$  and  $-36.0^\circ\text{C}$ , i.e.,  
 321 the temperature field between the onset of hydrohalite precipitation and the  
 322 seawater eutectic in the presence of gypsum and mirabilite. The fractional  
 323 crystallisation pathway (section 1) was used for this computation, which does  
 324 not allow further brine–mirabilite reaction during hydrohalite precipitation,  
 325 and so, it reflected the hydrohalite solubility experiments carried out using  
 326 protocol-3 (section 2.4). As will be shown, the FREZCHEM code accurately  
 327 computes hydrohalite equilibria in sea ice brines (section 3.4), thus justi-  
 328 fying its use here. The mass of hydrohalite precipitate extracted from the  
 329 FREZCHEM output at  $0.25^\circ\text{C}$  cooling steps was incorporated into a 1D  
 330 numerical model of first-year sea ice (Cox and Weeks, 1988) as described for  
 331 mirabilite in Butler et al. (2016b). The 1D model calculated the thickness  
 332 and bulk  $S_A$  depth profile of the ice pack as it grows in autumn–winter, and  
 333 accounts for brine drainage in permeable sea ice ( $T > -5^\circ\text{C}$ ) and the effect  
 334 of hydrohalite precipitation on brine salinity ( $T < -22.9^\circ\text{C}$ ). The model was  
 335 used to estimate the hydrohalite mass per unit mass of sea ice (0.5 cm depth

336 increments) at temperature  $T[H_i(T)$ , in  $\text{g kg}^{-1}$  sea ice] after desalination by

$$H_i(T) = H(T) \frac{S_i}{S_{\text{sw}}} \quad (2)$$

337 where  $H(T)$  is the hydrohalite mass at temperature  $T$  that would precip-  
 338 itate from 1 kg of Standard Seawater ( $S_A = 35.165 \text{ g kg}^{-1}$ ) based on the  
 339 FREZCHEM model output,  $S_i$  is the bulk  $S_A$  of the ice as calculated by the  
 340 1D model, and  $S_{\text{sw}}$  is the  $S_A$  of Standard Seawater. The incorporation of  
 341 hydrohalite precipitation dynamics into the sea ice model allowed evaluation  
 342 of its temporal depth distribution in sea ice as the modelled ice pack grows  
 343 throughout an Arctic winter.

### 344 3. Results

#### 345 3.1. Gypsum solubility and saturation state between 0.2 and $-22.2^\circ\text{C}$

346 The positive  $\Delta\text{Ca}^{2+}$  values during protocol-1 and protocol-2 experiments  
 347 (Table 3) indicate that the brine–gypsum equilibrium was attained by disso-  
 348 lution of the gypsum seed throughout the 0.2 to  $-22.2^\circ\text{C}$  temperature range,  
 349 and so the  $pK_{\text{sp,gypsum}}^*$  was determined from undersaturation. This becomes  
 350 evident in  $\Omega_{\text{gypsum}}$  remaining below 1 throughout this temperature range,  
 351 approaching, but not exceeding, saturation ( $\Omega = 1$ ) only at  $-6.8^\circ\text{C}$  (Fig-  
 352 ure 2; Table 3). The  $pK_{\text{sp,gypsum}}^*$  increased from 2.878 to 2.900 between 0.2  
 353 and  $-1.8^\circ\text{C}$ , which represents a slight reduction in gypsum solubility with  
 354 decreasing temperature at constant salinity in seawater (Figure 1; Table 3).  
 355 Between  $-1.8$  and  $-6.0^\circ\text{C}$ , the  $pK_{\text{sp,gypsum}}^*$  decreased from 2.900 to 2.587  
 356 with decreasing temperature in brines representative of conservative physi-  
 357 cal solute concentration. The  $pK_{\text{sp,gypsum}}^*$  was relatively stable ( $2.591 \pm 0.004$ ,  
 358  $n = 5$ ) between  $-6.8$  and  $-10.1^\circ\text{C}$ , and then increased measurably and  
 359 monotonically to 2.852 between  $-10.1$  and  $-22.2^\circ\text{C}$  in conditions of decreas-  
 360 ing temperature, increasing ionic strength, and increasingly reduced  $\text{SO}_4^{2-}$   
 361 via mirabilite precipitation from the brine before and during the gypsum

Figure 1: Measured  $pK_{\text{sp,gyypsum}}^*$  in equilibrium sea ice brines plotted alongside output from the FREZCHEM model both for the seawater (0 to  $-1.8$  °C), ice-brine ( $-1.8$  to  $-6.4$  °C), and ice-brine-mirabilite ( $-6.4$  to  $-22.2$  °C) equilibrium systems. Also plotted are the  $pK_{\text{sp,gyypsum}}^*$  measurements in full and equilibrium crystallisation conditions at  $-23.7$  and  $-25.0$  °C (see sections 2.4 and 3.3). The vertical line at  $-1.8$  °C marks the point of which the solubility product begins to become affected by coupled changes in salinity and temperature as a result of freezing. The fitted line is based only on measurements from synthetic and natural brines (square and circle markers) between  $0.2$  and  $-22.2$  °C. B = Brine, G = Gypsum, M = Mirabilite.

solubility experiments (Figure 1; Table 3). Mirabilite seed was not present during the gypsum solubility experiments in this temperature range, but the initial brine equilibrated with mirabilite before the gypsum solubility experiments (protocol-2) and, also, during the experiments. The  $\text{SO}_4^{2-}$  addition to the mirabilite-equilibrated brine via gypsum seed dissolution resulted in mirabilite supersaturation and further mirabilite precipitation from this brine. Mirabilite as a result of this gypsum dissolution reaction was identified by XRPD analysis of the solids recovered at the end of these experiments (section 2.1. The  $K_{\text{sp,gyypsum}}^*$  between  $-6.8$  and  $-22.2$  °C therefore represents

371 the brine–mirabilite–gypsum equilibrium.

### 372 3.2. Gypsum dynamics in conditions of metastable mirabilite supersaturation

373 In the experiments carried out under metastable conditions of mirabilite  
374 supersaturation at  $-7.1$  and  $-8.2$  °C, the initial brines had a composition  
375 equivalent to that resulting from physical solute concentration at ice–brine  
376 equilibrium. Mirabilite would almost certainly not precipitate by homoge-  
377 neous nucleation in these conditions, and so, these brines had  $\Omega_{\text{mirabilite}} =$   
378  $1.252$  and  $1.717$  at  $-7.1$  and  $-8.2$  °C, respectively, calculated from the  
379  $\Omega_{\text{mirabilite}} - T$  relationship in Butler et al. (2016b). Seeding these brines with  
380 gypsum resulted in a decrease in  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$ , with a  $\Delta\text{Ca}^{2+}:\Delta\text{SO}_4^{2-} =$   
381  $0.90 \pm 0.05$  (Table 4), indicating gypsum precipitation. Based on the  $pK_{\text{gypsum}}^*$   
382 determined at the brine–gypsum equilibrium of these experiments (Table 4),  
383 the saturation state of the initial ice–brine equilibrium condition was  $\Omega_{\text{gypsum}} =$   
384  $1.173$  at  $-7.1$  °C and  $1.379$  at  $-8.2$  °C. The measured  $\Delta\text{Ca}^{2+}$  indicates that  
385 the amount of gypsum precipitate at brine–gypsum equilibrium was  $3.8$  mmol  
386  $\text{kg}^{-1}$  at  $-7.1$  °C and  $7.5$  mmol  $\text{kg}^{-1}$  at  $-8.2$  °C.

387 The subsequent seeding of the brine–gypsum equilibrium solutions with  
388 mirabilite in the presence of the gypsum seed/precipitate resulted in an in-  
389 crease in  $\text{Ca}^{2+}$  and further reduction of  $\text{SO}_4^{2-}$  (Table 4), implying concurrent  
390 gypsum dissolution and mirabilite precipitation by heterogeneous nucleation,  
391 respectively. This suggests that, despite the  $\text{SO}_4^{2-}$  removal from solution as  
392 gypsum, the brines at brine–gypsum equilibrium remained in a metastable  
393 supersaturated state with respect to mirabilite. It is also apparent that the  
394 consequent  $\text{SO}_4^{2-}$  removal to mirabilite resulted in  $\Omega_{\text{gypsum}} < 1$ , facilitat-  
395 ing gypsum dissolution. Based on the  $\text{Ca}^{2+}$  difference between the brine–  
396 gypsum and brine–gypsum–mirabilite equilibrium (Table 4), the amount of  
397 gypsum that dissolved in the presence of mirabilite seed was  $4.7$  and  $9.1$   
398 mmol  $\text{kg}^{-1}$  at  $-7.1$  and  $-8.2$  °C, respectively. This amount of gypsum disso-  
399 lution exceeds the amount of gypsum precipitation at sustained metastable  
400 mirabilite supersaturation and brine–gypsum equilibrium (computed in the

Figure 2: The measured  $\Omega_{\text{gypsum}}$  in equilibrium sea ice brines between 0.2 and  $-22.2$  °C plotted alongside the output from the FREZCHEM model. The vertical line at  $-1.8$  °C marks the point of which the saturation state begins to become affected by coupled changes in salinity and temperature as a result of freezing, while that at  $-6.4$  °C marks the onset of mirabilite precipitation. The horizontal line at  $\Omega_{\text{gypsum}} = 1$  is used to highlight the transition between undersaturation ( $\Omega_{\text{gypsum}} < 1$ ) and supersaturation ( $\Omega_{\text{gypsum}} > 1$ ).

previous paragraph). This then indicates that gypsum should be unstable once mirabilite begins to form. The  $pK_{\text{sp,gypsum}}^*$  at brine–mirabilite–gypsum equilibrium obtained from these experiments was in close agreement with the  $pK_{\text{sp,gypsum}}^* - T$  relationship outlined in section 3.1 (Figure 1; Tables 3 and 4). This indicates that identical chemical equilibrium conditions can be attained independently of the order of mineral seeding/nucleation.

### 3.3. Gypsum solubility in the fractional and full crystallisation pathways

The brines used for the gypsum solubility measurements in conditions representative of fractional and full crystallisation pathways at  $-23.7$  and  $-25.0$  °C were extracted from the ice–hydrohalite aggregate in protocol-3

Table 4: Equilibrium measurements of  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  concentrations from experiments that investigated gypsum solubility in conditions of metastable mirabilite supersaturation at  $-7.1$  and  $-8.2$  °C. \* denotes solutions that were supersaturated with respect to mirabilite at the point of measurement. Tabulated errors are calculated as the standard deviation of measurements from triplicate experiments.

System	$T$ °C	$\text{Ca}^{2+}$	$\text{SO}_4^{2-}$	$pK_{\text{sp,gypsum}}^*$
		mmol $\text{kg}_{\text{sol}}^{-1}$	mmol $\text{kg}_{\text{sol}}^{-1}$	
Ice–brine*	$-7.1$	$33.8 \pm 0.1$	$91.9 \pm 0.6$	
Brine–gypsum*	$-7.1$	$30.0 \pm 0.1$	$88.0 \pm 0.6$	$2.578 \pm 0.002$
Brine–gypsum–mirabilite	$-7.1$	$34.7 \pm 0.1$	$73.2 \pm 0.2$	$2.595 \pm 0.001$
Ice–brine*	$-8.2$	$37.1 \pm 0.4$	$100.7 \pm 0.2$	
Brine–gypsum*	$-8.2$	$29.6 \pm 0.5$	$91.6 \pm 1.0$	$2.567 \pm 0.011$
Brine–gypsum–mirabilite	$-8.2$	$38.7 \pm 0.4$	$65.3 \pm 0.3$	$2.597 \pm 0.006$

experiments (section 2.4). These brines were at equilibrium with ice and hydrohalite but supersaturated with respect to gypsum because, when incubated only with gypsum seed (representative of the fractional crystallisation pathway), a negative  $\Delta\text{Ca}^{2+}$  was observed, implying 6.8 and 9.3 mmol  $\text{kg}^{-1}$  of gypsum precipitate at  $-23.7$  and  $-25.0$  °C, respectively (Table 5). This corresponds to  $\Omega_{\text{gypsum}} = 1.064$  and 1.069 in the brines of the ice–hydrohalite aggregate at  $-23.7$  and  $-25.0$  °C, respectively (Table 5). When these brines were seeded with both gypsum and mirabilite (representative of the full crystallisation pathway), the  $\Delta\text{Ca}^{2+}$  was more negative and the  $\Delta\text{SO}_4^{2-}$  less so than in the absence of mirabilite in the fractional crystallisation pathway at both temperatures (Table 5). The  $\Delta\text{Ca}^{2+}$  in these experiments is equivalent to 23.2 mmol  $\text{kg}^{-1}$  and 80.9 mmol  $\text{kg}^{-1}$  of gypsum precipitate at  $-23.7$  °C (corresponding to  $\Omega_{\text{gypsum}} = 1.257$  in the initial brine) and  $-25.0$  °C (corresponding to  $\Omega_{\text{gypsum}} = 2.276$  in the initial brine), respectively (Table 5). Collectively, these observations indicate enhanced gypsum precipitation in the presence of mirabilite, with the additional source of  $\text{SO}_4^{2-}$  provided by mirabilite dissolution.

The  $pK_{\text{gypsum}}^*$  determined at brine–hydrohalite–gypsum equilibrium (frac-

429 tional crystallisation pathway) was in close agreement with the values deter-  
 430 mined at brine–mirabilite–hydrohalite–gypsum equilibrium (full crystallisa-  
 431 tion pathway) at  $-25.0$  °C and within experimental uncertainty at  $-23.7$  °C,  
 432 despite differing equilibrium brine composition and inter-ionic ratios of  $\text{Ca}^{2+}$   
 433 and  $\text{SO}_4^{2-}$  (Table 5; Figure 1). This suggests that, within experimental error  
 434 at the two coldest temperatures of this investigation, the  $pK_{\text{gypsum}}^*$  is not  
 435 measurably influenced by differences in the equilibrium ionic composition of  
 436 the brine resulting from the fractional and full crystallisation pathways.

Table 5: Equilibrium measurements of gypsum solubility at  $-23.7$  and  $-25.0$  °C in experiments considered representative of fractional and full crystallisation. The  $\Omega_{\text{gypsum}}$  values presented here were based exclusively on the  $\Delta\text{Ca}^{2+}$ , since the  $\text{SO}_4^{2-}$  is affected by mirabilite dissolution.  $\Delta\text{Ca}^{2+} = \text{Ca}_{\text{eqm}}^{2+} - \text{Ca}_{\text{initial}}^{2+}$ .  $\Delta\text{SO}_4^{2-} = \text{SO}_{4\text{ eqm}}^{2-} - \text{SO}_{4\text{ initial}}^{2-}$ . Tabulated errors are calculated as the standard deviation of measurements from triplicate experiments.

Type	$T$ °C	$\text{Ca}^{2+}$	$\text{SO}_4^{2-}$	$pK_{\text{sp,gypsum}}^*$	$\Omega_{\text{gypsum}}$	$\Delta\text{Ca}^{2+}$	$\Delta\text{SO}_4^{2-}$
		mmol $\text{kg}_{\text{sol}}^{-1}$	mmol $\text{kg}_{\text{sol}}^{-1}$			mmol $\text{kg}_{\text{sol}}^{-1}$	mmol $\text{kg}_{\text{sol}}^{-1}$
Fractional	$-23.7$	$107.0 \pm 1.0$	$12.2 \pm 0.4$	$2.883 \pm 0.011$	$1.064 \pm 0.027$	$-6.8$	$-6.6$
Full	$-23.7$	$90.7 \pm 3.9$	$16.5 \pm 2.4$	$2.830 \pm 0.055$	$1.257 \pm 0.052$	$-23.2$	$-2.4$
Fractional	$-25.0$	$135.3 \pm 0.4$	$9.7 \pm 1.9$	$2.885 \pm 0.038$	$1.069 \pm 0.003$	$-9.3$	$-13.3$
Full	$-25.0$	$63.7 \pm 3.8$	$20.6 \pm 2.1$	$2.883 \pm 0.027$	$2.276 \pm 0.139$	$-80.9$	$-2.1$

### 437 3.4. Hydrohalite solubility and saturation state

438 The brine–hydrohalite equilibrium was attained by dissolution between  
 439  $-14.3$  and  $-22.0$  °C in protocol-2 experiments (section 2.4), as evidenced by  
 440 positive  $\Delta\text{Cl}^-$  (Table 6). In this temperature range, the  $pK_{\text{sp,hydrohalite}}^*$  (Fig-  
 441 ure 3) and  $\Omega_{\text{hydrohalite}}$  (Figure 4) increased from  $-1.175$  to  $-1.107$  and from  
 442  $0.465$  to  $0.953$  (Table 6), respectively, indicating a decrease in hydrohalite sol-  
 443 ubility with decreasing temperature at brine–hydrohalite equilibrium. Dur-  
 444 ing the protocol-3 experiments (section 2.4) at  $-23.7$  and  $-25.0$  °C, the ice–  
 445 brine–hydrohalite equilibrium was attained by precipitation as evidenced by  
 446 negative  $\Delta\text{Cl}^-$  values (estimated using FREZCHEM; see below and Table 6).  
 447 The  $pK_{\text{sp,hydrohalite}}^*$  increased sharply to  $-0.976$  at  $-25.0$  °C, representing a

dramatic decrease in hydrohalite solubility at  $T \leq -22.9$  °C (Figure 3) in the fractional crystallisation pathway.

Because it was not possible to determine  $\Omega_{\text{hydrohalite}}$  experimentally at  $-23.7$  and  $-25.0$  °C, the FREZCHEM code was used to compute the solution composition at ice–brine–mirabilite equilibrium at these temperatures by excluding hydrohalite and gypsum from the mineral database. At  $T \leq -22.9$  °C, the  $\Omega_{\text{hydrohalite}}$  increased steeply to 3.848 at  $-25.0$  °C (Figure 4). Because the  $pK_{\text{sp,hydrohalite}}^*$  from the experiments between  $-14.3$  and  $-25.0$  °C was in excellent agreement with that of the FREZCHEM model (Figure 3), the experimental values were combined with the FREZCHEM model output to derive the  $pK_{\text{sp,hydrohalite}}^* - T$  relationship (eq. 1; Table 2).

## 4. Discussion

This section will associate the laboratory measurements of gypsum and hydrohalite solubilities to their dynamics within the natural sea ice environment. Discussing hydrohalite dynamics in this context highlights its role within the sea ice system as a mediator of physical sea ice properties, and its contribution to geochemical changes that add to physiological challenges imposed upon sympagic biota. Discussing gypsum dynamics in this context aids in elucidating the conditions in which it can precipitate and persist in sea ice, and allows evaluation of its potential as a marine deposit.

### 4.1. Gypsum solubility in seawater and sea ice brines between 0.2 and $-22.2$ °C

The consistency in  $pK_{\text{sp,gypsum}}^*$  determined in both natural and synthetic sea ice brines between 0.2 and  $-5.0$  °C (Figure 1 ; Table 3) indicates that, as with mirabilite solubility (Butler et al., 2016b), gypsum solubility is unaffected by parameters such as pH, carbonate and borate alkalinity, and trace metals within the measurement uncertainty. By considering solutions either at equilibrium, or supersaturated, or undersaturated with respect to mirabilite, gypsum solubility was measured mostly via dissolution, with measurements via precipitation possible on a few occasions, in a range of scenarios

Table 6: The absolute salinity ( $S_A$ ) of incubated brines prior to seeding with hydrohalite (see footnote for exceptions), incubation temperature at point of sampling,  $\text{Na}^+$  and  $\text{Cl}^-$  concentrations from each of the bottle incubations at equilibrium, the resulting measured  $pK_{\text{sp,hydrohalite}}^*$  and  $\Omega_{\text{hydrohalite}}$ , and the change in  $\text{Cl}^-$  observed over the course of each experiment, included as a measure of reaction direction ( $\Delta\text{Cl}^- = \text{Cl}_{\text{eqm}}^- - \text{Cl}_{\text{initial}}^-$ ). All data above  $-22.9^\circ\text{C}$  are derived from dissolution of hydrohalite in solutions extracted from an ice–brine–mirabilite equilibrium system (see protocol-2, section 2.4). D = dissolution, P = precipitation. Tabulated errors are calculated as the standard deviation of measurements from triplicate experiments.

<sup>b</sup> Brine further cooled to target temperature, initiating ice and hydrohalite precipitation.

<sup>c</sup> Estimated from brine–mirabilite equilibrium using FREZCHEM.

relevant to sea ice. It is noted that these incubations do not account for the effect of ikaite precipitation on the availability of  $\text{Ca}^{2+}$  within the sea ice brine system, but this effect is predicted to be relatively minor (Butler et al., 2016a).

The current measurements of the stoichiometric solubility product of gypsum (Figure 1) indicated that seawater and the ice–brine and ice–brine–mirabilite equilibrium systems between 0.2 and  $-22.2^\circ\text{C}$  were all undersaturated with respect to gypsum, as reflected in the  $\Omega_{\text{gypsum}}$  remaining below 1 (Figure 2). Exception to this trend is a narrow temperature range of metastable mirabilite supersaturation between  $-6.4^\circ\text{C}$  and  $-8.2^\circ\text{C}$  that concurs with gypsum supersaturation, which can lead to gypsum precipitation (see section 4.2 for further discussion).

The equilibrium  $\text{Ca}^{2+}$  as a function of temperature between  $-6.4$  and

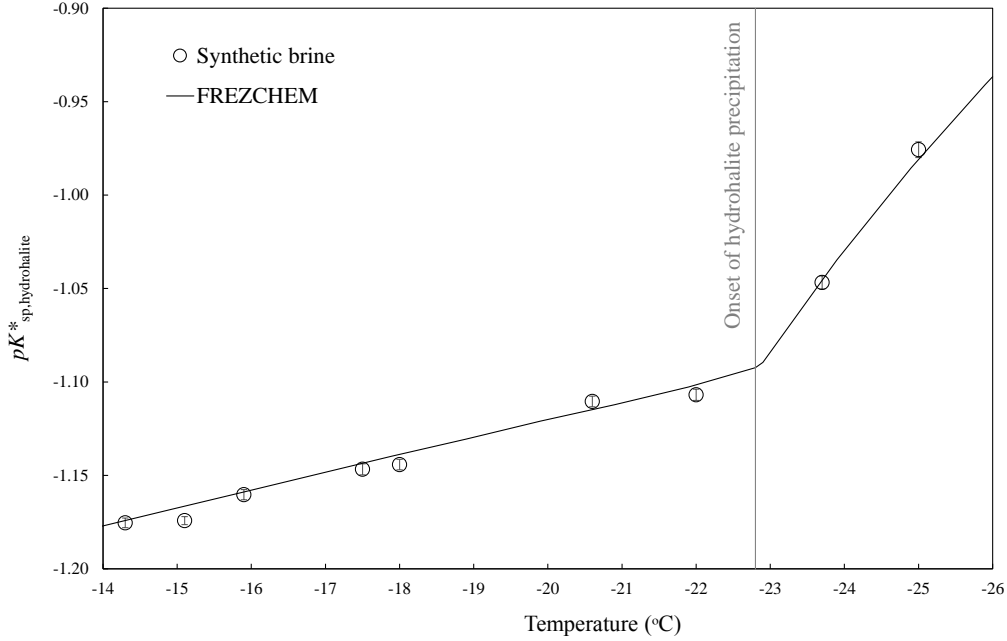

Figure 3: Measured  $pK^*_{sp,hydrohalite}$  in equilibrium sea ice brines plotted alongside the output from the FREZCHEM model. The vertical line at  $-22.9$  °C marks the point of which the solubility product begins to become affected by the precipitation of hydrohalite. All data above  $-22.9$  °C are derived from dissolution of hydrohalite seed in solutions extracted from an ice–brine–mirabilite equilibrium system (see protocol-2, section 2.4).

490  $-22.2$  °C (Figure 5, top panel) reflects the increase by both physical con-  
 491 centration of a cooling ice–brine system and the dissolution of the gypsum  
 492 seed in the current experiments, the latter reaction leading to higher  $\text{Ca}^{2+}$   
 493 than in conservatively concentrated seawater-derived brine at each experi-  
 494 mental temperature. In contrast, the decrease in equilibrium  $\text{SO}_4^{2-}$  between  
 495  $-6.4$  and  $-22.2$  °C reflects the imbalance between the processes that in-  
 496 crease  $\text{SO}_4^{2-}$ , i.e., the physical concentration of the brine during cooling of  
 497 the system and the dissolution of the gypsum seed during the experiments,  
 498 and the removal of  $\text{SO}_4^{2-}$  from the brine before and during the solubility ex-  
 499 periments via mirabilite precipitation (Figure 5, bottom panel). The  $\text{Ca}^{2+}$   
 500 at brine–mirabilite–gypsum equilibrium predicted by the FREZCHEM code

Figure 4: Measured  $\Omega_{\text{hydrohalite}}$  in equilibrium sea ice brines plotted alongside the output from the FREZCHEM model. The vertical line at  $-22.9$  °C marks the point of which the saturation state begins to become affected by precipitation of hydrohalite. The horizontal line at  $\Omega_{\text{hydrohalite}} = 1$  is used to highlight the transition between undersaturation ( $\Omega_{\text{hydrohalite}} < 1$ ) and supersaturation ( $\Omega_{\text{hydrohalite}} > 1$ ). All data above  $-22.9$  °C are derived from dissolution of hydrohalite in solutions extracted from an ice–brine–mirabilite equilibrium system (see protocol-2, section 2.4).

501 showed increasing deviation from the measured equilibrium concentrations  
502 with decreasing temperature below  $-10$  °C (Figure 5, top panel). This devia-  
503 tion was not observed between the measured and modelled equilibrium  $\text{SO}_4^{2-}$   
504 (Figure 5, bottom panel). The close agreement between code output and ob-  
505 servations as regards  $\text{SO}_4^{2-}$  reflects the mirabilite equilibrium ( $\Omega_{\text{mirabilite}} = 1$ )  
506 via precipitation before and during the brine incubation with gypsum, the  
507 latter fuelled by the excess  $\text{SO}_4^{2-}$  released into the brine via dissolution of the  
508 gypsum seed and supported by synchrotron XRPD (sections 2.1 and 3.1).

509 Direct comparison of the measured  $pK_{\text{sp,gypsum}}^*$  with values derived from  
510 the FREZCHEM output (section 2.5; Figure 1) shows that the FREZCHEM-

511 derived values follow the same trend with temperature as the experimentally  
 512 determined values, but the code overestimates the  $pK_{\text{sp,gypsum}}^*$  by  $0.069 \pm 0.024$   
 513 throughout the investigated temperature range. Between  $0.2$  and  $-10.1$  °C,  
 514 FREZCHEM underestimated the equilibrium  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  by  $2.03 \pm 0.98$   
 515 and  $3.14 \pm 3.05$  mmol kg<sup>-1</sup>, respectively (Figure 5). As mentioned above,  
 516 between  $-10.1$  and  $-22.2$  °C, the FREZCHEM computation of the equilib-  
 517 rium  $\text{SO}_4^{2-}$  was increasingly consistent with measurements, with deviations  
 518 decreasing from  $5.82$  to  $0.15$  mmol kg<sup>-1</sup>, as would be expected from the reli-  
 519 able representation of measured mirabilite equilibria by the thermodynamic  
 520 database of the code (Butler et al., 2016b). In contrast, the underestimation  
 521 of equilibrium  $\text{Ca}^{2+}$  by the code increased from  $1.54$  to  $25.33$  mmol kg<sup>-1</sup>  
 522 between  $-10.1$  and  $-22.2$  °C. This discrepancy was also seen in the  $\Omega_{\text{gypsum}}$   
 523 (Figure 2), with the FREZCHEM predictions consistently exceeding those  
 524 based on the experimental values. Between  $0.2$  and  $-22.2$  °C, the current  
 525 experiments indicate that gypsum would not exceed saturation in the pres-  
 526 ence of mirabilite in the sea ice brines but the FREZCHEM code shows two  
 527 regions of gypsum supersaturation: first between  $-6.4$  and  $-9.3$  °C, and  
 528 secondly at temperatures  $\leq -17.3$  °C (Figure 2).

529 Compared to its reliable computation of mirabilite (Butler et al., 2016b)  
 530 and hydrohalite (Figures 3 and 4) dynamics in sea ice brines, the thermody-  
 531 namic database of the FREZCHEM code yields gypsum dynamics in sea ice  
 532 brines inconsistent with the dynamics determined here. The inconsistency is  
 533 moreover particularly related to the modelled equilibrium  $\text{Ca}^{2+}$  between  $-10$   
 534 and  $-22.8$  °C (Figure 5). To predict gypsum solubility in the sea ice brines  
 535 presented here, FREZCHEM parameters have to be extrapolated into an  
 536 experimentally unknown region since the majority of relevant experimental  
 537 data has a minimum temperature of  $0$  °C (Marion and Farren, 1997; Mar-  
 538 ion and Kargel, 2008; Raju and Atkinson, 1990; Marion et al., 2016). Such  
 539 extrapolation is regularly applied at below-zero temperatures, and targeted  
 540 experiments would help improve on the currently observed discrepancies with

541 respect to gypsum solubility at these temperatures.

#### 542 4.2. Gypsum dynamics in metastable mirabilite supersaturation

543 The degree of gypsum supersaturation observed in brines that sustained  
544 metastable supersaturation with respect to mirabilite ( $\Omega_{\text{gypsum}} = 1.171$  at  
545  $-7.1$  °C, and  $\Omega_{\text{gypsum}} = 1.358$  at  $-8.2$  °C) would be predicted by extrap-  
546 olating the  $\Omega_{\text{gypsum}} - T$  relationship observed at ice–brine equilibrium be-  
547 tween  $-1.8$  and  $-6.0$  °C (Table 2, row 5) into this temperature region with  
548 commensurate physical concentration of the brine (Figure 2, cross markers).  
549 Thus, gypsum precipitation could occur in sea ice at temperatures below  
550  $-7$  °C if nucleation and crystal growth conditions are more favourable for  
551 this phase than for mirabilite. Even with gypsum precipitation under these  
552 conditions, mirabilite will remain supersaturated. The further the tempera-  
553 ture decreases below  $\sim -7.1$  °C, the greater the tendency for mirabilite to  
554 precipitate by homogeneous nucleation because its solubility in brines de-  
555 creases sharply with decreasing temperature (Butler et al., 2016b) while that  
556 of gypsum is essentially unchanging ( $pK_{\text{sp,gypsum}}^* = 2.59$ ) between  $-6$  and  
557  $-10$  °C (Figure 1). Subsequent mirabilite nucleation and precipitation in  
558 this temperature range will destabilize the gypsum completely. Therefore,  
559 over the  $-6.4$  °C to  $-22.2$  °C temperature range, mirabilite precipitation  
560 will dominate the compositional changes in the brine, with 92 % of  $\text{SO}_4^{2-}$   
561 removed from the brine as mirabilite by  $-20.6$  °C (Butler et al., 2016b).

562 Collectively the current results do not support the results of Gitterman  
563 (1937), who proposed gypsum to precipitate from synthetic seawater-derived  
564 brines below approximately  $-15$  °C. We instead propose that favourable  
565 conditions for gypsum precipitation in sea ice between  $-7$  and  $-22$  °C are  
566 entirely dependent on the occurrence of metastable mirabilite supersatura-  
567 tion conditions, which are increasingly unlikely as the temperature decreases  
568 within this range. The sea ice brine system will return to the ice–brine–  
569 mirabilite equilibrium and become undersaturated with respect to gypsum  
570 (Figure 2) once mirabilite authigenesis occurs. If gypsum precipitation oc-

571 curs via this mechanism in natural sea ice, its presence is therefore expected  
572 to be transient in the presence of mirabilite.

#### 573 *4.3. Fractional and full crystallisation pathways at $-23.7$ and $-25.0$ °C*

574 The more recent proposal for enhanced gypsum precipitation below  $-22.9$  °C  
575 (Marion et al., 1999) is relevant to the temperature region of hydrohalite pre-  
576 cipitation, ice formation, and significant reduction in brine volume (Richard-  
577 son, 1976; Butler and Kennedy, 2015), with consequent substantial shifts  
578 in solution composition and inter-ionic ratios, particularly with respect to  
579  $\text{Na}^+$ ,  $\text{K}^+$ ,  $\text{Mg}^{2+}$  and  $\text{Ca}^{2+}$  (Table 7). The precipitation of gypsum in the  
580 fractional and full crystallisation experiments was observed to occur over  
581 weeks, in accord with the slow kinetics of sulphate minerals at cold temper-  
582 atures (Kargel, 1991; Hogenboom et al., 1995; Marion and Kargel, 2008).  
583 The gypsum solubility experiments at  $-23.7$  and  $-25.0$  °C considered rep-  
584 resentative of the fractional crystallisation pathway (section 2.4), indicated  
585 that this compositional change is sufficient for the brine to become slightly  
586 supersaturated with respect to gypsum, resulting in its seeded precipitation  
587 (Table 5 and section 3.3). And so, the sea ice system appears to sustain a  
588 low gypsum supersaturation in the fractional crystallisation pathway within  
589 the ice–hydrohalite aggregate. In the tandem experiments, considered repre-  
590 sentative of the full crystallisation pathway, the presence of both mirabilite  
591 and gypsum seed in the experimental brine yielded mirabilite dissolution  
592 and gypsum precipitation in higher amounts than observed in the absence  
593 of mirabilite (Table 5 and section 3.3). These observations collectively indi-  
594 cate that, when all potential minerals are in contact with the brine in a sea  
595 ice system (full crystallisation pathway) at these cold temperatures, a posi-  
596 tive feedback will occur for gypsum precipitation via mirabilite dissolution in  
597 the presence of hydrohalite, as was also observed by Gitterman (1937) and  
598 Marion et al. (1999).

599 Combining the maximum amount of gypsum precipitation measured here  
600 at  $-25.0$  °C ( $\Delta\text{Ca}^{2+} = 80.9$  mmol  $\text{kg}^{-1}$  during full crystallisation; Table 5)

Figure 5: The equilibrium  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  concentrations in sea ice brines between 0.2 and  $-22.8$  °C. Measured and modelled (FREZCHEM) values above  $-6.4$  °C are at brine–gypsum equilibrium, and those below  $-6.4$  °C are at brine–mirabilite–gypsum equilibrium. The vertical line at  $-1.8$  °C marks the point at which coupled changes in salinity and temperature occur as a result of freezing, whilst that at  $-6.4$  °C marks the onset of mirabilite precipitation. The dashed line represents the estimated concentration based on a conservatively concentrated solution at ice–brine equilibrium, computed using FREZCHEM with only ice enabled in the mineral database.

with the FREZCHEM estimate of the residual brine mass at this temperature in a closed sea ice system (no brine drainage) from a starting practical salinity of  $35 \text{ g kg}^{-1}$  ( $64.9 \text{ g}$  of brine per  $\text{kg}$  frozen seawater), we estimate a maximum gypsum concentration in bulk sea ice of  $0.9 \text{ g kg}^{-1}$  at  $-25.0 \text{ }^{\circ}\text{C}$ . In comparison, the estimated concentrations of mirabilite and hydrohalite in undrained bulk sea ice at the same temperature and full crystallisation pathway are  $6.7$  and  $28.6 \text{ g kg}^{-1}$ , respectively.

#### 4.4. *Hydrohalite solubility in sea ice brines*

The excellent agreement between the experimentally determined  $pK_{\text{sp,hydrohalite}}^*$  and that computed by FREZCHEM reflects the abundance of experimental data for hydrohalite used to parameterise the model. All experimental (Gitterman, 1937; Nelson and Thompson, 1954; this study) and model (Marion et al., 1999; Marion and Kargel, 2008) evidence is in agreement that hydrohalite precipitates in sea ice at  $T \leq -22.9 \text{ }^{\circ}\text{C}$ , but its dynamics in undersaturated sea ice brines have never been investigated before. Between  $-14$  and  $-25 \text{ }^{\circ}\text{C}$ , the solubility of hydrohalite (Figure 3) displays two distinct temperature fields corresponding with the undersaturated and supersaturated brines (Figure 4), with a sharp inflection at  $\Omega_{\text{hydrohalite}} = 1$ . This sharp change is reflected in the quantity of hydrohalite in a closed sea ice brine system (no brine drainage), which, by  $-23.0 \text{ }^{\circ}\text{C}$ , i.e.,  $0.1 \text{ }^{\circ}\text{C}$  into the temperature region in which its precipitation is viable in sea ice systems, amounts to  $3.3 \text{ g kg}^{-1}$ , and increases to  $28.0 \text{ g kg}^{-1}$  by  $-26.0 \text{ }^{\circ}\text{C}$  (fractional crystallisation; Figure 6). Such quantities of hydrohalite are consistent with the formation of an ice–hydrohalite aggregate (Light et al., 2009; McCarthy et al., 2007; Butler and Kennedy, 2015).

Prior to the onset of hydrohalite precipitation,  $\text{Na}^+$  and  $\text{Cl}^-$  comprise  $91.7 \%$  of the total mass of dissolved ions in the brine (FREZCHEM computation, Table 7). Upon hydrohalite precipitation, the reduced ionic strength of the brine from the removal of  $\text{Na}^+$  and  $\text{Cl}^-$  as hydrohalite promotes instantaneous ice formation to re-establish ice–brine equilibrium at these cold

Table 7: FREZCHEM predictions of the major brine composition before ( $-22.8\text{ }^{\circ}\text{C}$ ) and after ( $-26.0\text{ }^{\circ}\text{C}$ ) hydrohalite precipitation. Each ion is presented as its percentage contribution to the mass of total salt. The output at  $-26.0\text{ }^{\circ}\text{C}$  is for fractional crystallisation, which retains the brine at undersaturation with respect to mirabilite. The displayed percentages are implicit of less concentrated ions that are also specified in the composition of Standard Seawater (Millero et al., 2008), which include  $\text{HCO}_3^-$ ,  $\text{CO}_3^{2-}$ ,  $\text{NO}_3^-$ ,  $\text{Br}^-$ ,  $\text{B}(\text{OH})_4^-$ ,  $\text{F}^-$  and  $\text{CO}_2$ . Ice, mirabilite and hydrohalite were the only solid phases enabled in the FREZCHEM database for this computation.

Ion	$-22.8\text{ }^{\circ}\text{C}$	$-26.0\text{ }^{\circ}\text{C}$
	$S_A = 230.82\text{ g kg}_{\text{sol}}^{-1}$	$S_A = 235.68\text{ g kg}_{\text{sol}}^{-1}$
% $\text{Na}^+$	29.89	20.00
% $\text{K}^+$	1.36	2.91
% $\text{Mg}^{2+}$	4.36	9.31
% $\text{Ca}^{2+}$	1.38	2.95
% $\text{Cl}^-$	61.77	64.59
% $\text{SO}_4^{2-}$	0.62	1.06

temperatures, which concentrates the brine and results in further hydrohalite precipitation. This cycle of both ice and hydrohalite formation in tandem continues until ice–brine–hydrohalite equilibrium is attained; in the process, the volume of remaining brine diminishes. Between  $-22.8$  and  $-26\text{ }^{\circ}\text{C}$  in a closed system modelled with FREZCHEM (1 kg of seawater, practical salinity = 35), the amount of ice increases from 857 g to 909 g, which decreases the amount of liquid water from 105 to 41 g (Figure 7). In sea ice, this would equate to a reduction in brine volume by more than 60 % within a  $3\text{ }^{\circ}\text{C}$  drop in temperature.

If hydrohalite precipitation in sea ice results in the formation of an ice–hydrohalite aggregate, then the in-situ properties of this solid may be analogous to those studied in the  $\text{NaCl-H}_2\text{O}$  system at its eutectic (McCarthy et al., 2007). The formation of an ice–hydrohalite aggregate may act as a hindrance for the hydrohalite–mirabilite–gypsum interaction with the residual brine of the full crystallisation pathway (Gitterman, 1937; Marion et al., 1999). Mirabilite crystals are understood to sink to the bottom of brine inclusions (Light et al., 2003); when hydrohalite forms as an aggregate with ice

with the residual brine trapped in it, it will fill the available pore space and can consequently restrict further brine–mirabilite interaction. The result is a microstructure with very limited mixing and surface area for brine–mineral interaction, acting to limit the dissolution of mirabilite and the consequently enhanced precipitation of gypsum. Although the hydrohalite–mirabilite feedback was observed by Butler and Kennedy (2015), their experimental protocol required continual spinning of the sample, which may have promoted mineral interaction with brine by mixing as the sample warmed and cooled. The determination of which crystallisation pathway occurs in the temperature field of hydrohalite precipitation in natural sea ice conditions requires further investigation, and would likely require in-situ measurements in controlled laboratory conditions that replicate those in sea ice.

#### 4.5. *Hydrohalite modelling in first-year sea ice*

The dynamics of hydrohalite in first-year sea ice are outlined here based on the FREZCHEM output, confirmed by the current hydrohalite solubility data, and a 1D empirical model of sea ice growth and desalination. The FREZCHEM output of the mass of hydrohalite to precipitate in a 1 kg parcel of frozen seawater (Figure 6) was fitted to a stepwise polynomial function of temperature (Table 2, rows 11 and 12). This data was integrated (via equation 2) into a 1D model simulation of the vertical temperature and salinity profiles of snow-free first-year sea ice in the Arctic Basin as it grows over winter months, yielding hydrohalite concentration profiles within the ice pack at selected intervals (Figure 8). The temperature at the surface of the modelled ice pack drops below  $-22.9\text{ }^{\circ}\text{C}$  after 1 month (early November) from the onset of freezing when the ice pack is 73.5 cm thick and the incoming shortwave radiation for the region is  $0\text{ W m}^{-2}$ . Between early November and late February, the modelled ice pack thickens to 210 cm, while the surface temperature decreases to  $-32.1\text{ }^{\circ}\text{C}$ . Given the absence of sunlight and low temperatures, these conditions likely represent the most challenging and least studied aspects of Arctic sea ice dynamics.

Figure 6: The weight of hydrohalite predicted to precipitate from 1 kg of seawater (practical salinity = 35) between  $-22.9$  and  $-36$  °C (fractional crystallisation). Also plotted is the fitted relationship of hydrohalite concentration ( $\text{g kg}^{-1}$ ) as a function of temperature (using equation 1) described by coefficients given in Table 2.

As the ice pack thickens and the surface temperature decreases, the modelled hydrohalite concentration increases (Figure 8). When the ice pack is 75 cm thick, hydrohalite is only present in the upper 1 cm but, as the winter progresses, the vertical distribution of hydrohalite extends well below the ice surface, and by mid-February, when the ice is over 2 m thick, hydrohalite is present within the upper 65 cm. The depth distribution of hydrohalite in the ice is governed by the bulk sea ice salinity and the temperature-related solubility changes leading to precipitation (Figure 6), while the sea ice temperature is assumed to have a linear depth distribution between the ice-air and ocean-ice interfaces (Cox and Weeks, 1988; Butler et al., 2016b). As a result of these two forcings, hydrohalite develops an S-shaped depth profile as the ice pack grows, reaching a maximum concentration below the ice-air

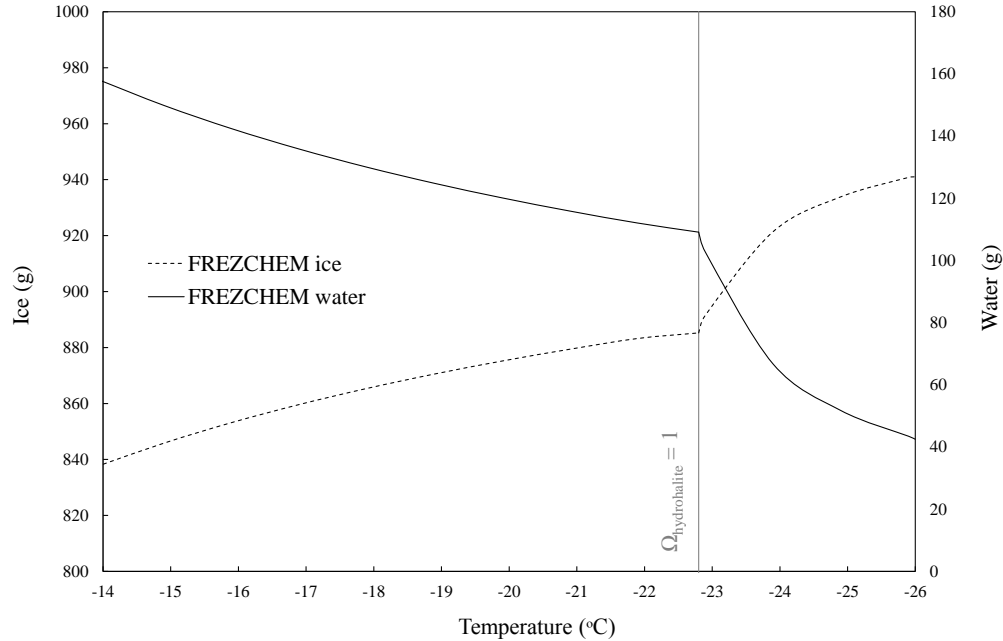

Figure 7: FREZCHEM predictions of the change in ice and water content in 1 kg of frozen seawater (practical salinity = 35) between  $-14$  and  $-26$  °C (fractional crystallisation). The vertical line at  $-22.9$  °C marks the point of which the system begins to become affected by precipitation of an ice–hydrohalite aggregate.

690 interface of  $9.9 \text{ g kg}^{-1}$ .

691 Based on its solubility–temperature relationship (Figures 3, 4 and 6),  
692 the occurrence of hydrohalite in sea ice could display considerable daily  
693 or localised shifts between precipitation and dissolution in response to lo-  
694 cal weather patterns. Given that hydrohalite precipitation did not initiate  
695 within the modelled ice pack until incoming shortwave radiation had reduced  
696 to  $0 \text{ W m}^{-2}$ , its contribution to the albedo feedback mechanism (Light et al.,  
697 2004; Carns et al., 2015) in polar environments seems limited, and is likely to  
698 be more relevant to the energy balance of ‘Snowball Earth’ during the Neo-  
699 proterozoic (Light et al., 2009; Carns et al., 2015). Furthermore, the winter  
700 conditions in which hydrohalite precipitates likely hinder its identification  
701 and the examination of its dynamics in the sea ice system in the field.

Figure 8: Modelled hydrohalite concentrations during the formation of first-year snow-free sea ice in the Arctic Basin. The full depth of the ice pack is not displayed, but is instead annotated at each increment.

#### 4.6. The occurrence of gypsum in sea ice

The available mirabilite (Butler et al., 2016b), gypsum, and hydrohalite solubility data (this study) can be used to evaluate the potential for occur-

705 rence of gypsum in sea ice. The tendency of gypsum formation is strongly  
 706 constrained by  $\text{SO}_4^{2-}$  availability in the brine, first, due to mirabilite precip-  
 707 itation at temperatures  $\leq -6.4$  °C and, subsequently, via mirabilite disso-  
 708 lution at temperatures  $\leq -22.9$  °C. The recent identification of gypsum in  
 709 experimental and natural sea ice at temperatures between  $-1.9$  and  $-10$  °C  
 710 (Geilfus et al., 2013) is not consistent with the systematic gypsum undersat-  
 711 uration observed here between  $0.2$  and  $-22.2$  °C in the presence of mirabilite  
 712 (section 4.1 and Figure 2). Furthermore, the gypsum crystals identified in  
 713 the experimental sea ice formed during the freezing of synthetic seawater that  
 714 was deficient in  $\text{Ca}^{2+}$  and  $\text{SO}_4^{2-}$  by 17 % and 40 %, respectively, relative to  
 715 Standard Seawater (Geilfus et al., 2013). The deficiency of this solution with  
 716 respect to the ionic constituents of gypsum would only act to impede this  
 717 mineral from attaining saturation within the brine in the reported tempera-  
 718 ture range that includes the temperature region of mirabilite precipitation.  
 719 Our experiments showed that brines in metastable mirabilite supersatura-  
 720 tion state can attain low gypsum supersaturation leading to precipitation of  
 721 this  $\text{CaSO}_4$  polymorph in small amounts, which will be likely transient in  
 722 the presence of mirabilite given its dominant control on the availability of  
 723 sulphate ions in the brine. It is possible that the brief storage ( $< 3$  hours) of  
 724 sea ice samples  $< -25$  °C prior to analysis carried out by Geilfus et al. (2013)  
 725 allowed gypsum precipitation, which could become enhanced if hydrohalite-  
 726 mirabilite-gypsum interaction with brine is facilitated, but the quantity of  
 727 gypsum formed in this way would be small ( $< 0.3 \text{ g kg}_{\text{sea ice}}^{-1}$  at a bulk salinity  
 728 of  $12 \text{ g kg}^{-1}$ ) even if chemical equilibrium is attained.

729 Finally, the gypsum crystals that were observed in experimental and  
 730 natural sea ice (Geilfus et al., 2013) may not have been authigenic but al-  
 731 lochthonous. Though the gypsum crystals were identified as authigenic based  
 732 on their grain morphology (Geilfus et al., 2013), gypsum is also a common  
 733 mineral in aerosol particles (Prospero et al., 1981; Schütz and Seibert, 1987;  
 734 Zimmermann et al., 2008) which are understood to be the source of its pres-

ence in ice cores taken from the Greenland Ice Sheet (Biscaye et al., 1997; Steffensen, 1997). Gypsum can persist in an ice sheet due to its sparing solubility in aqueous solutions (Steffensen, 1997). Therefore, gypsum may not occur authigenically in brine inclusions but in aerosols settling on, and encapsulated in, sea ice, and may be sufficiently stable kinetically to allow extraction and identification even when the conditions in the brine pockets are undersaturated with respect to gypsum. Given this generated understanding about gypsum dynamics in sea ice from solubility measurements, particularly with respect to its undersaturation in all conditions above  $-6.4$  °C, its potential as a marine deposit in polar seas (Geilfus et al., 2013) seems limited.

## 5. Conclusions

The determination of gypsum and hydrohalite solubilities in seawater (gypsum) and seawater-derived brines (gypsum and hydrohalite) allowed investigation of the dynamics of each mineral within the sea ice system. Gypsum solubility changed substantially between  $0.2$  and  $-25.0$  °C, displaying maximum solubility (i.e., minimum values for the stoichiometric equilibrium solubility product) in the temperature range from  $-6$  °C to  $-10$  °C, with decreasing solubility at warmer and colder temperatures. The precipitation of gypsum is affected by the precipitation of mirabilite at temperatures below  $-6.4$  °C. When mirabilite is the dominant  $\text{SO}_4^{2-}$  sink in sea ice, the brines remain undersaturated with respect to gypsum to  $-22.2$  °C. Gypsum is viable as a transient phase in conditions of metastable mirabilite supersaturation as observed in this study at  $-7.1$  and  $-8.2$  °C but potentially applicable to occurrences of increased metastable mirabilite supersaturation at colder temperatures. Upon the onset of hydrohalite precipitation at temperatures below  $-22.9$  °C, gypsum can precipitate and, when the brine–mirabilite reaction is viable in these cold temperatures, mirabilite dissolution consequent on hydrohalite precipitation can enhance the amount of gypsum precipitate

764 to approximately  $0.9 \text{ g kg}^{-1}$  (closed seawater system) at  $-25.0 \text{ }^{\circ}\text{C}$ .

765 The solubility of hydrohalite in sea ice decreases with temperature, and  
766 this decrease displays a sharp change at  $-22.9 \text{ }^{\circ}\text{C}$ , resulting in distinct tem-  
767 perature fields of undersaturated and supersaturated brines. The sharp  
768 change in hydrohalite solubility at temperatures below  $-22.9 \text{ }^{\circ}\text{C}$  results from  
769 the formation of an ice–hydrohalite aggregate. During this process, ice and  
770 hydrohalite form cooperatively as an intergrowth, likely displaying similar  
771 properties to the eutectic aggregates from binary  $\text{NaCl-H}_2\text{O}$  systems (Mc-  
772 Carthy et al., 2007). This heterogeneous mixture can fill the sea ice pores  
773 and channels, and results in strong compositional changes in the little brine  
774 that remains at these cold temperatures, affecting the microstructure of the  
775 ice substantially.

776 The observed gypsum solubility is consistently underestimated by the  
777 thermodynamic FREZCHEM code. This inconsistency was assessed here to  
778 be associated with the discrepancy in the equilibrium  $\text{Ca}^{2+}$  concentration,  
779 likely due to the model being extrapolated into an experimentally unknown  
780 region. In contrast the measured and FREZCHEM-based hydrohalite sol-  
781 ubilities display excellent agreement (within experimental error). Based on  
782 the reliable FREZCHEM output of hydrohalite equilibria, a temperature  
783 function of the hydrohalite mass in a closed sea ice system was incorporated  
784 into a 1D model for the growth of Arctic sea ice. The model output of the  
785 distribution of hydrohalite with time and depth in sea ice showed that hydro-  
786 halite should be present in the upper layers of the ice pack once the incoming  
787 shortwave radiation drops to  $0 \text{ W m}^{-2}$ , extending down to a depth of 65 cm  
788 in the ice from a  $9.9 \text{ g kg}^{-1}$  surface concentration maximum at maximal  
789 ice thickness. This suggests a critical role for hydrohalite in modifying the  
790 physical and chemical properties of the sea ice brine inclusions but limited  
791 hydrohalite effect on the albedo of sea ice.
