The Great Zab River catchment is a major left-bank tributary of the River Tigris and drains a substantial part of the Kurdistan Region, an autonomous region of Northern Iraq. Within Kurdistan, the water resources of the Great Zab River catchment are under pressure from population increase and are utilized for potable, domestic and agricultural and industrial supply. As with many parts of the world, effective management of water resources within Kurdistan is hindered by a lack of water quality data and established background concentrations. This study therefore represents the first regional survey of river water chemistry for the Great Zab River catchment and presents data on the spatial and temporal trends in concentrations of As, Ba, Ca, Cd, Co, Cr, Cu, Fe, Hg, Li, Mn, Mo, Ni, Pb, Sr, Zn, NO$_3^-$, SO$_4^{2-}$, F$^-$, Cl$^-$, and PO$_4^{3-}$, in addition to pH, electrical conductivity, dissolved oxygen and turbidity. As a tool for underpinning the management and monitoring of water quality, background concentrations were defined for the Great Zab catchment using three methods. The influences of geogenic and anthropogenic controls upon spatial and temporal trends in water chemistry are also evaluated. The influence of geogenic loading from underlying bedrock was identifiable within the observed spatial trends, with the most notable differences found between waters sampled from the relatively more volcanic-rich Zagros Zone to the north and those sampled from the lower catchment underlain by younger clay-, sand- and siltstones. The greatest anthropogenic influence, identifiable through elements such as Cl$^-$ and NO$_3^-$, is present in the more highly-populated lower catchment. The background concentrations identified in the Great Zab catchment would be those expected as a result of geogenic loading with some anthropogenic influence and represent a more conservative value when compared to those such as the World Health Organization Maximum Admissible Concentration. However, background concentrations represent a powerful tool for identifying potential anthropogenic impacts on water quality and informing management of such occurrences.

KEY WORDS: ambient background; water quality; management; Kurdistan
INTRODUCTION

As noted by Adams and Chapman (2007), compared to organic substances, metals in surface waters pose significant regulatory challenges given that they may be sourced from natural geogenic loading as well as anthropogenic inputs, and that the latter may be highly spatially variable and diffuse in nature. Furthermore, anthropogenic inputs may stem from historical activities long-since ceased (e.g. Alpers et al., 2005).

A major step in developing a regulatory framework for surface water quality is the derivation of background concentrations (Oste et al., 2012). Determining a background concentration may be used to set a threshold value, which may allow instances of contamination of water to be identified (Panno et al., 2006). Background can be considered to be a concentration of a substance resulting from natural processes, uninfluenced by human activity (Reimann and Garrett, 2005). Given the spatial variability in factors determining geogenic metal loading to surface waters, ‘global’ background values are therefore of limited use (Oste et al., 2012). As a result, developing regional background concentrations can be seen as preferable. Given the difficulty in finding waters that have no anthropogenic ‘signal’ (Smith et al., 2003), the term ‘ambient background concentrations’ has been developed, whereby concentrations represent natural and low level anthropogenic inputs (Peters et al., 2012). Approaches to defining background concentrations in surface waters have been reviewed by detail by Oste et al. (2012).

Ensuring water quality is a key component of ensuring sufficient water supply as part of water resources management. This is particularly relevant to the provision of potable water supplies. Pressures on water quality have been noted in catchments and regions experiencing population and industrial growth (McDonald et al., 2011; McDonald et al., 2014).

The Kurdistan region is experiencing rapid increase in population. This combined with an increased urban population and improvements in living standards have resulted in pressures on water resources through impacts upon water quality (Alobaidy et al., 2010). These pressures are being felt, in conjunction with the threat posed from climate change, across the globe (Vörösmarty et al., 2000). The Great Zab River catchment represents one of the largest catchments in the Kurdistan Region, covering an area of approximately 40,643 km$^2$ and surface waters in the catchment provide water supply to a population of 1.8 million. Effective management of water resources through legislative control on water quality is currently being restricted by a lack of national water quality guidelines (Shareef and Muhamad, 2008). Whilst there has been some study of water quality in particular parts of the catchment (e.g. Abdulwahid, 2013; Shareef et al., 2009; Shareef and Muhamad, 2008; Toma, 2011a; Toma, 2011b), there has been no attempt to establish baseline water chemistry and define...
background concentrations that may act as a means of evaluating water quality, and which may form
the basis for the development of appropriate legislative guidelines.

The aims of this study are therefore to address this knowledge gap by determining ambient
background concentrations for the Great Zab River catchment for 16 metals, 5 anions, pH, electrical
conductivity (EC), dissolved oxygen (DO) and turbidity and to evaluate the spatial and seasonal trends
in water quality within the catchment.

STUDY AREA

Kurdistan occupies an area of 40,643 km² and a population growth rate is 2.7% per annum (Ministry of
Planning, 2011), notably in the cities of Erbil, the capital city, Sulaimaniya and Dohuk, is placing
pressure upon water resources. Stevanovic and Iurkiewicz (2009) report that that population growth
has led to the decline in the per capita availability and use of water resources. According to the
Ministry of Planning/KRG (2011), the quantity of water produced on a daily basis is 924,600 m³, while
daily demand totals approximately 1.25 million m³. Therefore, the present water supply deficit is
325,400 m³ per day, i.e. 26% of total demand and 35% of total quantity produced at present.

The Great Zab River catchment covers an area of approximately 40,300 km², with 13,708 km² within
Kurdistan and the remainder in Turkey. The Great Zab River is a left bank tributary of the River Tigris,
with confluence downstream of Mosul. The flow regime of the Great Zab River is strongly influenced
by annual snowmelt, with the highest monthly mean discharges occurring in the early summer months
(Saleh, 2010). Within Kurdistan, the Great Zab catchment sits within three major geological zones
(Figure 1). To the northeast, the Zagros Zone comprises predominantly folded limestones with some
felsitic volcanics. The Imbricated and High-fold zones comprise Cretaceous-age carbonates in a range
of different formations. A detailed description of these has been produced by Sissakian (2013),
however, in summary these formations comprise predominantly limestone that has been variably
pervaded by dolomite, marl and shale. The lower portion of the catchment lies within the Foothill zone
(Figure 1), dominated by late Miocene to Pleistocene-aged sandstones, siltstone and claystone
(Sissakian, 2013). The region at the boundary of the High-fold and Foothill zones comprises a number
of formations of generally Paleocene and Eocene age that comprise dolomitic limestones and,
particularly to the northwest, thick basaltic lavas (Sissakian, 2013).
METHODS

Samples of river water were collected from 62 sites in February 2014 and June 2014 (Figure 1). Sample sites were selected to best balance the demands of ease of access and spatial coverage, with sample sites focusing mainly upon road-river intersections (c.f. Bird et al., 2010). In the field, samples were filtered through 0.45 μm cellulose nitrate filter membranes, acidified with 50% HNO₃ and placed on ice in acid-washed Nalgene bottles. Samples were stored below 5°C prior to analysis. Concentrations of As, Ba, Ca, Cd, Co, Cr, Cu, Fe, Hg, Li, Mn, Mo, Ni, Pb, Sr, Zn were determined by Inductively Coupled Plasma Mass Spectrometry (Agilent Technologies 7700). Analytical accuracy was assessed through the analysis of the NIST1643 certified reference material and analytical precision through the repeat analysis (n = 10% of total sample number) of a randomly selected sample. Data for analytical quality control are given in Table 1. Samples were analysed by ion chromatography for their NO₃⁻, SO₄²⁻, F⁻, Cl⁻, and PO₄³⁻ content. A Thermo Fisher AS22 anion exchange column was used for the separation of SO₄²⁻, F⁻, Cl⁻, and PO₄³⁻. The mobile phase was 4.5 mM sodium carbonate/1.4 mM sodium bicarbonate and flow rate 1.2 ml/min. Suppression was achieved using a Metrohm Suppressor Module, supplied with a 150 mM sulphuric acid/0.1 M oxalic acid/acetone mix and ultrapure water. Inorganic anions were detected using a suppressed conductivity detector. All solutions were prepared in ultrapure water with a specific resistance of (18.2) MΩ cm (Millipore, Molsheim, France). Analytical accuracy on anion analyses (Table 1) was assessed through the analysis of standard solutions and analytical precision through the repeat analysis (n = 10% of total sample number) of a randomly selected sample.

RESULTS AND DISCUSSION

Water chemistry

A summary of minimum, mean, median and maximum values is provided for cations (Figure 2), anions (Figure 3) and pH, EC, DO, turbidity (Figure 4). Global median and World Health Organization (WHO) Maximum Admissible Concentrations (MACs) also plotted in order to provide context for the data from Kurdistan. WHO MACs are appropriate for potable water, which is consistent with the Great Zab River, and provides an indication of water quality in relation to human health. In addition, percentage cumulative frequency plots of the water chemistry data for cations (Figure 5) and anions, pH, EC, DO, turbidity (Figure 6) show the frequency distribution of the parameters in summer and winter. Arsenic, and Hg were non-detectable in all samples.
In comparison to world median values, cation concentrations in the Great Zab catchment vary by metal (Figure 2). All Li and Ca concentrations are greater than the world median value, whilst the third quartile concentration for Ba is greater than the world median concentration. Third quartile concentrations for Cu, Zn and Pb are lower than the respective world median concentrations. For metals for which a WHO MAC has been defined, all concentrations in the Great Zab catchment fall below these.

All anion concentrations measured in the Great Zab catchment fall below their respect WHO MACs (Figure 3). All F⁻ and NO₂⁻ concentrations measured in the Great Zab catchment fall below world median concentrations, however a majority of sites had SO₄²⁻ concentrations in excess of the world median. The median Cl⁻ concentration in the Great Zab (6.7 mg l⁻¹) is largely similar to the world median concentration of 8.3 mg l⁻¹.

The pH of river water ranges from mildly acidic (5.6) to mildly alkaline (8.9). The turbidity of water (1.7-65 NTU) indicate that in general river water in Great Zab River catchment contains relatively low concentrations of suspended organic and inorganic material. Electrical conductivity ranges from 200 to 1028 µS cm⁻¹ with a median value of 375 µS cm⁻¹.

A Pearson Product Moment correlation was performed to evaluate bivariate relationships between water chemistry parameters. The full correlation matrix is included as Supplementary Material and Fe, As and Hg were not include in the analysis due to the high number of non-detectable concentrations. Statistically significant correlations between cations and anions are relatively rare, notable exceptions being between SO₄²⁻ (r = 0.408) and NO₃⁻ (r = 0.441) and Ba; both significant at α = 0.01. Statistically significant correlation between cations and between anions are more frequent. With respect to cations, significant correlations exist between metals in the same groups, such as between the transition metals. Particularly strong correlations exist between Ni and Co (r = 0.801), Cu (r = 0.659) and Zn (r = 0.816). For alkaline earth metals, strong correlation relationships exist between Ca and Sr (r = 0.822) and Ba (r = 0.349). Significant correlations exist between a number of anions (see supplementary data), being strongest between F⁻ and SO₄²⁻ (r = 0.637). There are relatively few significant correlations between elemental concentrations and pH; Ca, Ba, Cl⁻ and NO₃⁻ being exceptions. Dissolved oxygen concentrations are correlated with PO₄³⁻ and SO₄²⁻ (α = 0.01).

In order to establish whether water chemistry differs significantly between summer (lower flow conditions) and winter (generally higher flow conditions), data collected in February 2014 and June 2014 were compared using a one way ANOVA on log-transformed data, using a significance threshold of α = 0.05. Results (Table 2) indicate that concentrations of Ca, Li, Mo are higher in the
winter than summer (statistically significant at $\alpha = 0.05$), whilst concentrations of Zn, $\text{SO}_4^{2-}$, $\text{F}^-$, $\text{Cl}^-$, and $\text{PO}_4^{3-}$ are higher in the summer than winter (statistically significant at $\alpha = 0.05$). Seasonal
differences for other analytes were not statistically significant. Higher concentrations of a number of
elements during winter (higher discharge conditions) in the Great Zab catchment suggests enhanced
delivery from the riparian zone via a combination of surface and sub-surface flows. Calcium, Li and
$\text{SO}_4^{2-}$ concentrations have been found to be consistently higher than world median concentrations.

The relationship between water quality and river discharge is a potentially complex scenario.

Previous studies (e.g. Garbarino et al., 1995) have reported generally higher concentrations of
metals under low flow conditions due to a lower degree of physical dilution that occurs during
periods of low discharge. In addition, higher discharge conditions can result in a reduction in
dissolved concentrations due an increase in sorption process due to higher suspended sediment
concentrations. However, conversely other studies (e.g. Gundersen and Steinnes, 2001) have
demonstrated that periods of higher discharge can yield higher metal concentrations due to
enhanced delivery of substances to the river channel from run-off and the potential activation of
point sources. What is apparent is that different elements can display different relationships with
discharge, as noted in a study of Southeast Asian rivers by Chanpiwat and Sthiannopkao (2014).

In an attempt to evaluate the spatial trends in water quality, samples were grouped based upon the
major underlying geological units identified in the Great Zab catchment. The groups were identified
as: 1) Zagros Zone, 2) the Imbricated/High-folded Zone and 3) the Foothill Zone (Figure 1). The
grouping by underlying geology, reflects the importance of geogenic loading in determining surface
water chemistry (Drever, 1997). Log-transformed data were analysed using a one way ANOVA, using
a significance threshold of $\alpha = 0.05$. The most frequent differences were found between water
chemistry in samples collected from the Zagros and Foothill Zones, with 13 parameters showing a
statistically significant difference (Table 2). Five and 7 parameters, respectively showed statistically
significant differences between the Zagros and Imbricated/High-fold Zones and Imbricated/High-fold
and Foothill Zones. The greater statistical similarity of water chemistry sampled in the
Imbricated/High-fold and Foothill Zones will reflect the greater similarity in bedrock geology
between these areas than compared with the Zagros Zone. The influence of geology on water
chemistry is exemplified by Ca and Sr concentrations; these are found to be significantly higher in
waters within the Imbricated/High-fold and Foothill Zones than in the Zagros Zones (Table 2).
Average Sr concentrations in water with the Imbricated/High-fold ($542 \mu g \text{ l}^{-1}$) and Foothill Zones ($683 \mu g \text{ l}^{-1}$) are at least twice as high as in the Zagros Zone ($243 \mu g \text{ l}^{-1}$). Average Ca concentrations are c.
10 mg l$^{-1}$ lower in the Zagros Zone compared to the Imbricated/High-fold and Foothill Zones. This
reflects the abundant carbonate bedrocks, notably limestone and dolomitic limestone, which are the main sources of Sr to stream water in particular, whilst the bedrock of Zagros Zone is relatively carbonate poor.

Chloride and NO$_3^-$ show a statistically significant difference between the Foothill Zone (the lower Great Zab catchment) and the two upstream zones (Table 2). Concentrations of Cl$^-$ and NO$_3^-$ are significantly higher in the lower catchment (Figure 7), as indicated by mean concentrations of 14.2 and 6.8 mg l$^{-1}$, respectively, which are twice as high as those for the Zagros and Imbricated/High-fold Zones upstream. Chloride and NO$_3^-$ are two elements for which higher concentrations in river water, and particularly within-catchment variability, can be the result of anthropogenic inputs, such as from agricultural activity in the case NO$_3^-$ (Randall and Mulla, 2001). Importantly, the amount of anthropogenic activity is greatest in the lower Great Zab catchment, the part of the catchment containing the highest Cl$^-$ and NO$_3^-$ levels. Whilst concentrations are below respective WHO MACs, the data exemplify and indicate that whilst geogenic inputs are important in explaining large scale variability in water chemistry, the spatially variable influence of anthropogenic activity is an important contributor to the water chemistry of the Great Zab catchment.

Quantifying background conditions

Establishing background geochemical conditions, provides a potentially valuable regulatory tool for evaluating water quality. However, given the difficulty in locating ‘pristine’ water bodies that have no anthropogenic influence, as reviewed by Peters et al. (2012), a range of approaches have been utilized to quantify background conditions in river catchments. Peters et al. (2012) used a low percentile of water quality data to provide a relatively conservative estimate of background, or what can be termed ‘ambient background’. In contrast, other approaches have utilized higher percentile, such as the 90$^{th}$ percentile value (Fraters et al., 2001).

To evaluate the potential influence of the approach used, three different approaches were taken. Firstly, background conditions were calculated as the 10$^{th}$ percentile value (Peters et al., 2012) of the whole dataset from the Great Zab River catchment (Table 3). Secondly, based upon the analysis of Q-Q plots of NO$_3^-$ concentrations, utilized as an anthropogenic marker, and other water quality parameters (Figure 8), the 95$^{th}$ percentile was identified as a point where the distributions differ (Helsel and Hirsch, 2002). Therefore this is indicative of a different sample population above the 95$^{th}$ percentile and can be interpreted as a separation of geogenic and anthropogenic components (Table 3). Finally, following the method of Davies (1983) background concentrations were estimated using
regression analysis of % cumulative frequency curves of log10 concentrations from the sample population (Table 3).

Generally, of the three approaches, the 10th percentile concentrations are always the lowest (Table 3), with the exception of Ca and Sr, for which the regression-derived concentrations are lowest. The 10th percentile concentrations have been described by Peters et al. (2012) as reflecting ambient background conditions that, in relation to the Great Zab catchment, would be expected resulting from natural, geogenic inputs and low level anthropogenic activity. However, utilizing NO₃⁻ concentrations as an anthropogenic marker, suggest that the proportion of the sample population that could be considered as geogenic is much larger, equating to the 95th percentile value, and that background concentrations could potentially be established at higher concentrations.

Given that background concentrations may be used as an indicator of water quality, the background concentrations can be compared to WHO MACs (Table 3). All background concentrations in the Great Zab, determined by the three methods used, are lower than WHO MACs. In some case, background concentrations are orders of magnitude lower, for example in the case of Cu and Zn (Table 3). The comparison to WHO MACs suggests that the background concentrations defined by this study can be viewed as very conservative if used as a guide for water quality based upon risks posed to human health. It is not suggested that the background concentrations derived here are adopted as a measure to protect human health, however, the concentrations quantified may act as a valuable guide for identifying instances for anthropogenic pollution within the Great Zab catchment.

Variations in water chemistry within the catchment would mean that the instances of enrichment above background concentrations varies between waters from the Zagros, Imbricated/High Fold and Foothill Zones. By way of example, comparison of Li, Ba, F⁻ and NO₃⁻ concentrations, which have been shown to differ significantly between the three zones (Table 2), suggests that instances of elevation above background concentrations vary between zone and element (Figure 9). Highest NO₃⁻ concentrations occur in the Foothill Zone, in waters from the Great Zab River itself, but also its tributaries, the Khazir River and the Gomal. NO₃⁻ concentrations in 7% of samples from Foothill zone exceed the 95th percentile-defined background value, but samples from the Zagros and Imbricated/High Fold Zones do not. Conversely, Li and F⁻ concentrations in the Zagros Zone, in 9% and 7% of samples respectively, exceed the 95th percentile-defined background value, with all samples in the two downstream zones falling below. These data further highlight that spatial trends in water chemistry, including the occurrence of relative elevation in concentrations, are likely to reflect both geogenic influences operating at larger spatial scales and site-specific conditions,
particularly point sources associated with anthropogenic activity, that vary between different water quality parameters.

CONCLUSIONS

This study has conducted and presented data for the first regional survey of river water chemistry for the Great Zab River catchment, a major left-bank tributary of the River Tigris. Data analysis has shown that concentrations in river water of Ca, Li, Mo, Zn, F⁻, Cl⁻, SO₄²⁻ and PO₄³⁻ are significantly different during summer and winter sampling periods, however, there are variations in terms of when concentrations are highest for different elements. The Great Zab catchment can be divided into three major geological units, and the influence of bedrock geology upon surface water chemistry is evidenced by differences in elemental concentrations in waters sampled from the different units. In addition, whilst elemental concentrations in the Great Zab are below WHO MACs, a potential anthropogenic influence on water chemistry is identifiable through the location of highest elemental concentrations. The lower catchment, which is most highly populated contains highest elemental concentrations and represent areas of concern for water resources management.

Background concentrations for the Great Zab catchment have been quantified using the 10th and 95th percentile concentrations and a regression analysis. These concentrations could be used as the basis for establishing water quality norms for the catchment and potentially the broader Kurdistan region. Comparison to WHO MACs, which provide human-health oriented guidelines for water quality, indicates that the use of a background concentration as a guide for water quality management, would produce much more conservative and stricter quality limits. This suggests that there is a potentially significant difference between background concentrations, which may be used to identify instances of contamination within a catchment and guidelines that establish potential threats to human health. The use of a guideline such as a WHO MAC as a measure of water quality in water quality assessments may actually mask instances of poor water quality that are identified via the establishment of a catchment-wide background concentrations.
