Abstract

Many have asserted that Sacred Natural Sites (SNS) play an important role in nature protection but few have assessed their conservation effectiveness for different taxa. We studied sacred groves in Epirus, NW Greece, where a large number of such SNS have been identified. Based on historical, ethnographic and ecological criteria, we selected eight of these groves and matching control sites and in them we studied fungi, lichens, herbaceous plants, woody plants, nematodes, insects, bats and passerine birds. Our results reveal that the contribution of SNS to species conservation is nuanced by taxon, vegetation type and management history. We found that the sacred groves have a small conservation advantage over the corresponding control sites. More specifically, there are more distinct sets of organisms among sacred groves than among control sites, and overall biodiversity, diversity per taxonomic group, and numbers of species from the European SCI list (Species of Community Interest) are all marginally higher in them. Conservationists regard the often small size of SNS as a factor limiting their conservation value. The sizes of SNS around the globe vary greatly, from a few square meters to millions of hectares. Given that those surveyed by us (ranging from 5 to 116 ha) are at the lower end of this spectrum, the small conservation advantage that we testified becomes important. Our results provide clear evidence that even small-size SNS have considerable conservation relevance; they would contribute most to species conservation if incorporated in networks.

Keywords

Sacred Natural Sites; Conservation value; Biodiversity; Extinction Debt; Beta diversity

Research highlights

➢ Sacred Natural Sites (SNS) are thought to play an important role in conservation but quantitative analyses are rare.

➢ We studied the conservation capacity of SNS at multiple sites for multiple taxonomic groups.

➢ The SNS studied deliver a small but important conservation benefit compared with corresponding control areas.

➢ The contribution of SNS to species conservation is nuanced by taxon, vegetation type and management history.

➢ The best conservation strategy for small SNS is to join them as parts of networks within conventional conservation schemes.

Sacred Natural Sites: SNS

Species Abundance Relationships: SAR

1. Introduction

Conservation is closely aligned with modern ecological thinking and over the last two centuries has become a major factor in policy decisions (Klein et al., 2009; Keppel et al., 2015). Before the arrival of the modern ecology-motivated concept, conservation has been practiced for many centuries in a variety of more traditional, community-based forms (Malhotra et al., 2007). One such form was through social taboos and religious beliefs that prescribed management regimes in sacred areas, often imposing limitations on certain activities, so as to secure important resources and services for the whole community (Berkes et al., 2000; Colding et al., 2001, Klepeis et al. 2016). These are the so-called sacred natural sites (SNS) that not only reflect the religious and social needs of the community but at the same time contribute important ecosystem services, from inspiration to air regulation, water and micro-climate quality, or conservation of biological diversity (Jim, 2003; Soury et al., 2007; Yuan and Liu, 2009; Wassie et al., 2010).

Sacred natural sites have been found in all inhabited continents (Hughes and Chandran, 1998) and woodland sacred groves can be traced back to the time when human society was still in a pre-agricultural state (Gadgil and Vartak, 1976). They have been associated with a wide range of faiths and beliefs, socio-cultural systems, institutions and ritual practices, and may be subject to changing conditions (Verschuuren et al., 2010). Around the Mediterranean basin, forests have long been recognized as a resource with a multifunctional role that needs particular care and protection. Groves or specific tree species, related mainly to sacrifice and burial, were considered as sacred and thus gained a special protection status (Blondel and Aronson, 1999). This was normally achieved through restrictions imposed by a local authority, usually a religious authority, threatening transgressors with supernatural consequences (Byers et al., 2001; Virtanen, 2002). At the same time, extended sacred forests served as a protective levee for the local community against natural disasters, such as landslides and floods (Stara et al., 2016). Sacred groves had flourished in Greece, since the Ottoman period, mainly in the mountainous regions, where the above-mentioned natural threats to local communities were much more severe and where historical circumstances allowed the involvement of the Church in their management.

Epirus is a mountainous region in northwestern Greece, in which sacred groves are a prominent component of the landscape; they form habitats dominated by mature trees that are unique within the historically intensively used landscapes (Stara et al., 2015; Stara et al.,

2016). These groves were established through a range of ritual praxes. Some were dedicated to specific saints, some were little more than community agreements, while others were protected by the threat of excommunication. Different management regimes prevailed through time with some groves being strictly protected, some subjected to controlled management, whereas for others only the protection of mature trees is reported. The groves appear either in the form of protective forests above or close to villages or as groups of veteran trees that accompany outlying churches or icon stands (Stewart, 1993; Nixon, 2006; See also Appendix G). Nonetheless, they served in many cases as multifunctional forests for local communities providing among others shaded grazing areas for livestock. Especially in deciduous sacred forests, grazing could be intensive (Papanastasis et al., 2008).

Different cultural groups coexisted in Epirus contributing to the variability of the landscape, but they were all associated with sacred groves. Long-term ethnographic research has revealed that of the 80 villages in the mountainous municipalities of Zagori and Konitsa almost all had at least one sacred grove; these groves mostly lie within a narrow range of elevation, typically from 800 to 1200 m (Stara et al., 2016). This is also the zone where most mountain settlements, characterized by a mixed system of agriculture-animal husbandry, have developed historically (Nitsiakos, 2016).

Even though the role of SNS in the conservation of biodiversity has long been recognized (Kosambi, 1962; Gadgil and Vartak, 1976; Haridasan and Rao, 1985), they have recently gained more attention amongst conservation biologists because of the many threats to biodiversity due to anthropogenic activities (Pimm et al., 1995; Gao et al., 2013). It has been suggested that incorporating these SNS into existing protected area networks might increase their effectiveness in achieving conservation objectives (Bhagwat and Rutte, 2006; Soury et al., 2007; Corrigan et al., 2013; Ormsby, 2013).

Despite the increasing interest in SNS as biodiversity refugia (Dudley et al., 2009), few studies have assessed their effectiveness across taxa, whilst most have focused on specific groups of organisms, such as plants (Boraiah et al., 2003; Khumbongmayum et al., 2006; Frascaroli et al., 2016), small mammals (Decher, 1997; Reed and Carol, 2004) or butterflies (Nganso et al., 2012). Most of these studies have been carried out in Asia, particularly India and China (Nganso et al., 2012; Gao et al., 2013; Karthikeyan and Dhamatharan, 2015), or Africa (Daye and Healey, 2015), with very little work in Europe (e.g. Frascaroli et al., 2016). It could be argued that, as most SNS tend to be small, their relevance to conservation, though

138   tangible, is limited compared to large reserves (Bossart et al 2006, Aerts et al 2006). Area is

139   expected to affect the conservation effectiveness of SNS in several important ways. Firstly,

140   the species-area relationship indicates that smaller areas cannot support as many species as

141   larger ones. If a habitat shrinks, the level of biodiversity that it can sustain in the long term

142   also shrinks, but, in the short term, the habitat retains more species than it can support. This

143   surplus is called "extinction debt" (Diamond, 1972) and it must eventually be paid. The

144   process takes time, with the magnitude of the delay being greater in larger fragments (Halley

145   et al., 2016). Both the extinction debt and the time to the new equilibrium are also affected by

146   the degree of isolation and the habitability of the "matrix" (i.e. the area between fragments;

147   Koh and Ghazoul, 2010).

148   Focusing on a group of sacred groves in Epirus, the goal of this study is to investigate the

149   conservation effectiveness of SNS. We do this by assessing their biodiversity and comparing

150   them with matched control sites. For each sacred grove, a nearby woodland area without any

151   sacred status but with similar characteristics was chosen to serve as a control site. To achieve

152   a substantial breadth of studied organisms, eight different taxonomic groups were

153   investigated simultaneously. Estimates of diversity were assessed per taxonomic group and

154   per site. The importance of the size of the groves was also explicitly considered. In addition,

155   extensive ethnographic research highlighted the impact of different management practices on

156   the conservation status of these groves. The specific hypotheses that we are testing are as

157   follows: (I) sacred groves have a higher alpha-diversity than their control sites because they

158   enjoyed greater protection; (II) alpha-diversity differences will be accentuated for taxa, such

159   as fungi or lichens, that benefit from the presence of trees of great age; and (III) sacred groves

160   have higher beta-diversity than their control sites, since each sacred grove is expected to have

161   its own distinctive land-use history (and therefore forest structure).

162   **2. Materials and Methods**

163   **2.1. Study Areas and Sampling**

164   Numerous sacred groves have been identified in a wide area of north-western Greece (Fig. 1),

165   of which 22 were mapped. Of these, eight (1S-8S) were selected for the current study, based

166   on an integrated set of historical, ethnographic, management and ecological criteria

167   (Appendices A and G). Each of the selected sacred groves is situated in the mountainous

168   region of Zagori and Konitsa (Fig. 1). Since our main hypotheses are that sacred-grove status

169   involves higher biodiversity, for each grove we chose a single non-sacred site attempting an

assessment of biodiversity differences as practiced in other similar studies (Wortley et al.
2013, Derhé et al. 2016). We selected control sites (1C-8C) in close proximity; these
matched each sacred grove in terms of substrate, topographic position and type of vegetation.
In this study, we identified three types of groves in terms of vegetation: those dominated by
(i) coniferous, (ii) evergreen broadleaved or (iii) deciduous broadleaved trees. We sampled in
these eight pairs of sites over two consecutive years (2013 and 2014) following a sampling
protocol that was adapted to the unique characteristics of each taxonomic group (Appendix
B). The sampling effort was the same across all sites for any given taxonomic group, so that
estimates of biodiversity are comparable.

2.2. Dataset

In total, eight taxonomic groups (fungi, lichens, herbaceous plants, woody plants, nematodes,
insects, bats and passerine birds) were sampled in each sacred grove and the corresponding
control site. All observed organisms of these groups were identified to species level, except
for nematodes, which were identified to genus level. The data consist of abundance records
per species, except for lichens, herbaceous plants (including ferns) and woody plants, for
which only species presence was recorded.

2.3. Biodiversity analysis

The biodiversity we assess here is the total number of species recorded in each site, which we
call the *species richness* of the site.

2.3.1. Ordination

To visualize the difference in composition between sites, multidimensional scaling analysis
based on Bray-Curtis dissimilarity was conducted for each taxon, separately, and for all taxa
combined. This index is widely used as a measure of multidimensional "distance" between
samples for abundance data (e.g. Clarke et al., 2007; Birtel et al., 2015; Nicol et al., 2017); it
has the advantage, over some other ordination techniques, that differences in abundance are
scaled proportionally . The analysis was implemented in R 3.2.3 (R Core Team, 2015) using
function *isoMDS* of the MASS package (Venables and Ripley, 2002) and function *vegdist* of
the VEGAN package (Oksanen et al., 2016).

2.3.2. Species richness

199   Sacred groves and control sites were compared in terms of their species richness per site

200   (across all taxa), total species richness per taxon (across all sacred and all control sites) and

201   species richness per site per taxon.

202   Apart from their *type* (sacred or control), sites are characterized by their *location* within the

203   region of Epirus (Fig. 1), their *vegetation* (three forest types) and the *area* of the site (being

204   the area of the convex hull containing the sample plots within each site) (Table 1).

205   To investigate the effect of the different site characteristics on species richness, a generalized

206   linear regression model *S ~ area + type + vegetation type + area:type* with Poisson response

207   and a logarithmic link function was used. The model is applied to the total species richness

208   per site and to the species richness of each taxonomic group per site. In addition, we carried

209   out a number of tests (regression and paired *t*-test) comparing species richness in sacred sites

210   and control areas with and without conifer groves.

211   We also recorded the numbers of European SCI, Species of Community Interest (Official

212   Journal of the European Union, 2009; Council Directive, 1992), for all sacred groves and

213   corresponding control sites (Table E.1). We assessed the significance of the differences

214   between them using a paired Students *t*-test.

215   *2.3.3. Beta diversity*

216   Apart from the species richness per site (alpha diversity) and the species richness across sites

217   (gamma diversity), the sacred and control site communities were compared in terms of their

218   beta diversity or species turnover (Magurran, 2004). Beta diversity between the local scale

219   (sites) and the global scale (union of sites) was measured using Whittaker index and N^* index

220   (Lazarina et al., 2013). Both indices give a measure of species turnover in space, which in

221   this case measures the difference in species composition between the local scale (site) and

222   global scale (the union of all sacred or all control sites). N^* is roughly defined as the

223   sampling effort (number of samples) above which the samples accumulated will mostly

224   contain species that have already been found. The advantage of the N^* index, as opposed to

225   other indices, is that it is independent of the sampling effort, provided that there are enough

226   samples for the index to be calculated (Lazarina et al 2013). The N^* index was computed

227   using the R function provided by Lazarina et al (2013). We tested the significance of

228   differences between sacred groves and control sites at the 5% level.

229   All statistical tests and analyses were performed in R 3.2.3 (R Core Team, 2015).

230 *2.3.4. Conservation capacity of SNS*

231 By the term "conservation capacity" we refer to the ability of a protected area to conserve
232 biodiversity, assuming that management measures to protect the site are implemented.
233 Conservation capacity involves two components: the number of species that an area of a
234 given size can support at equilibrium, based on the species-area relationship (SAR, see for
235 example Halley et al., 2013), and the duration for which the area can retain species (if fully
236 protected). This is based on an estimation of the species relaxation curve for extinction debt
237 (Halley et al., 2016), a prominent factor in extinction ecology and conservation (Newmark et
238 al., 2017). Extinction debt becomes important when a fragment of habitat within a larger
239 habitat network connected by dispersal gets isolated, with no further dispersal possible.
240 Thereafter, the viability of each species is dependent on its population size within the
241 fragment so that current species richness may be a relic of earlier biodiversity levels rather
242 than true conservation capacity. The conservation capacity of the sacred groves was
243 estimated for each taxonomic group, separately, using the Arrhenius SAR:
244

$$S = cA^z \qquad \qquad \text{...(1)}$$

245 The constant z is typically between 0.2 and 0.3 for islands, while for continental areas it falls
246 within the range of 0.1 to 0.15 (Halley et al., 2013). Calibration of the SAR was achieved by
247 assuming a continental area with exponent 0.15; then c was determined by using the number
248 of species found in the control sites through the formula $c = S/A^z$.

249 The first time-constant of relaxation is the expected time for half the extinction debt to be
250 paid off, which actually is the half-life of extinction debt in a habitat remnant. In the absence
251 of speciation and colonization, the half-life of extinction debt is equal to the time for species
252 richness to fall to half its original value. Based on the models developed in Halley et al.
253 (2016), this is approximately (in years):

254
$$t_{50} \approx 2.77 \left(\frac{\rho A}{S_0} \right)^{\alpha} \tau \qquad \qquad \text{...(2)}$$

255 Here, A is the area of the remnant forest, ρ is the typical total density of individuals of the
256 relevant taxonomic group, τ is the average generation time and S_0 is the initial number of
257 species in the area A at the time of area reduction or isolation. The factor $\rho A/S_0$ is important,
258 being the number of individuals per species. If the initial number of species, S_0, is not known,
259 the alternative is to use the SAR and substitute Eq. (1) for species number:

$$260 \qquad\qquad t_{50} = 2.77 \left(\frac{\rho A^{1-z}}{c} \right)^{\alpha} \tau \qquad\qquad\qquad ... (3)$$

260 $\qquad$

261 In order to get ρ and τ, we assume a single average for each taxonomic group (Halley et al.,

262 2016). For passerine birds, herbaceous and woody plants, ρ and τ values are as in Halley et

263 al. (2016). For nematodes, our measurements indicated typical densities of 7.5×10^9

264 individuals per ha and we used a generation time of 19 days (Lee, 2002), while for bats we

265 used ρ=0.105 individuals per ha and for the generation time we used τ=8 years, which is half

266 the average longevity (Austad and Fischer, 1991). For insects, the value of τ=1 year was

267 typical of the species in our study, while ρ=7.83$\times10^4$ individuals per ha that we used is

268 clearly a conservative number as it refers to ground-dwelling beetles (Didham et al., 1998).

269 We did not compute curves for lichens or fungi owing to known complications of defining

270 individuals and generation times for these groups.

271 *2.3.5. SNS and National Parks (NP) size worldwide*

272 To see how the size of the sacred groves that we studied fits into the global picture, using a

273 literature search, we assembled a database of SNS from various countries, for which we could

274 find the area (Table F.1) as well of National Parks in three countries: Greece, the United

275 Kingdom and the United States (Table F.2).

276 **3. Results**

277 In total, across all taxonomic groups studied, 816 species were observed and identified within

278 the eight pairs of sacred groves and control sites (Table C.1). There was great variability in

279 the species richness of the sacred sites relative to their respective control sites for different

280 taxonomic groups: in five of them, the total number of species observed was higher in the

281 sacred groves, and in three groups, it was higher in the control sites (Fig. 2a), but these

282 differences were not statistically significant except for fungi (p=0.001, see Table C.2), for

283 which richness was higher in sacred groves. Combining species across the taxonomic groups,

284 all except two localities had higher species richness in the sacred grove than the

285 corresponding control site (Fig. 2b). The two exceptions are localities 4 and 7 (Fig. 1) that are

286 associated with steeper slopes and are dominated by conifers. The other six pairs are

287 associated with the lowland or southern-aspect slopes and are dominated by broadleaved

288 trees. There is a strong correlation (Fig. 2b) between the species richness of the sacred groves

289 (x) and control sites (y) in each locality for the six pairs dominated by broadleaved trees,

290   reflecting the success of their matching in the sample design ($y=0.727x+30.56$, $R^2=0.912$,

291   $p=0.003$). For these localities, there is also a significant difference between overall species

292   richness in the sacred groves and control sites (*t*-test, $p=0.0085$). These tests show a

293   consistent trend for greater overall species richness in the sacred groves than the control sites.

294   Ordination shows that the patterns of species composition amongst the three vegetation types

295   (Fig. D.1) varied by taxonomic group. However, with species of all groups combined, there

296   was a clear distinction between the vegetation types. Regarding the site type, there were no

297   consistent differences in composition between sacred groves and control sites for the

298   individual groups of species or for all species combined (Figs D.1 and D.2). The generalized

299   linear regression analysis shows (Table C.2) that the site area and type do not affect

300   significantly the total species richness per site (at a 5% significance level). However, their

301   interaction is significant meaning that the relationship between species richness and area

302   differs depending on the type of the site (sacred or control). As sacred sites are mostly

303   smaller in area than control sites (Table 1). The total species richness is also significantly

304   affected by vegetation type. On a taxonomic group level, the locality is not significant for any

305   group. The type of the site (sacred or control) is significant only for fungi, whereas vegetation

306   type is significant for lichens, herbaceous plants, and woody plants; none of these predictors

307   is significant for nematodes, insects, passerine birds or bats. The interaction between site

308   locality and type is also significant for herbaceous plants and lichens, as was also the case for

309   total species richness.

310   Of the 13 European SCI species that were encountered in the study area, more were found in

311   the sacred groves (eleven) than in their control sites (nine) especially for passerine birds (8

312   versus 4). However, overall the difference was not significant (paired *t*-test; $p=0.30$).

313   The Whittaker and N^* indices of species turnover reveal significantly greater beta diversity

314   amongst the sacred groves than amongst the control sites (at the 5% level for both indices)

315   (Fig. 3). More specifically, beta diversity is greater in the sacred groves for five taxonomic

316   groups (lichens, herbaceous plants, woody plants, passerine birds and bats); it is slightly less

317   for insects, and very similar between the two site types for nematodes and fungi. Notably,

318   beta diversity is much lower for the nematodes than for all the other taxonomic groups of

319   species, presumably because nematodes were identified only to genus level and, hence, the

320   majority of nematode genera are found in all samples.

The area of the sacred groves was small, ranging from 4.9 ha to 115.7 ha with a median size of 18.4 ha. Both the area and the taxonomic group are expected to affect the half-life of species loss following habitat isolation (Fig. 4a) and, hence, their conservation capacity. The predicted half-life varied greatly amongst taxonomic groups being low for bats and passerine birds, under 100 years for most of the sacred groves, but very high, above 1000 years, for nematodes and herbaceous plants (because of their large populations) and for woody plants (because of large generation times)). However, the general linear modelling analysis did not find a significant relationship between area and species richness.

In our literature search, we found 104 SNS for which the area was recorded or could easily be inferred; these occur in all inhabited continents. To these we added the 22 sacred groves in Epirus that we mapped, including the 8 whose biodiversity we studied in detail. The histogram for this ensemble (Fig 4a) shows that the size of SNS varies greatly, ranging from a few square metres to over 100,000 km^2, with the groves that we studied falling in the smaller part of the range. By contrast, National Parks are always at least 10 km^2 (Fig. 4b).

4. Discussion

Globally, this is the first study to evaluate the conservation capacity of SNS by use of a large and taxonomically broad set of species. Regarding Hypothesis (I), our study shows that while sacred groves contained more species overall, the difference between them and control sites was not statistically significant unless the north-facing conifer sites were omitted from the analysis. Similar statistical issues have arisen in a previous study comparing protected and unprotected areas for several taxonomic groups (Gray et al., 2016), despite the expected differences between such areas. These results suggest that the advantage of protected over unprotected areas becomes blurred when more than one taxonomic group is examined (Khumbongmayum et al., 2005; Gao et al., 2013). To avoid the bias of masking differences when pooling together data from different taxonomic groups, in the present study, biodiversity was assessed for each group separately. While species richness was higher for most groups in sacred groves, only for fungi was this difference significant. This lends support to Hypothesis (II), except that for lichens, the other taxon that should benefit from the presence of older trees, the differences were not significant. For plants, this lack of strong distinction contrasts with an earlier study (Frascaroli et al., 2016) reporting significantly more species in sacred groves than in reference sites. In contrast to the nuanced difference in

species richness between sacred groves and control sites, there was a clear biodiversity benefit when beta diversity was considered (Hypothesis III). Its higher value for sacred groves suggests that there is a greater distinction (in the sets of species) between sacred groves than between control sites. This might be explained by the groves different histories of usage, which have a significant effect on sacred grove's vegetation structure and therefore on the ecological community structure, thus increasing the dissimilarities between groves. Different patterns of land abandonment could also play a role. By contrast, the ~~non sacred~~ control areas arose largely through natural regeneration in the last 100 years and thus have a more uniform structure.

Given the lack of evidence of a strong difference in species richness or composition between sacred groves and control sites, other factors were explored to explain the results found. The most obvious candidate was vegetation type, as the eight pairs of sites were stratified between topographic locations, with three different vegetation types being distinguished, dominated by coniferous, evergreen broadleaved or deciduous broadleaved trees. In all of the analyses, and for many of the species groups examined separately, a clear distinction was found in species richness and composition between the six site pairs dominated by broadleaved trees (with either similar overall richness between the site types or higher richness in the sacred groves) in contrast to the two site pairs with conifer-dominated vegetation (where control sites had higher richness). Other than the nature of coniferous forests *per se*, a number of features might also contribute to the distinct biodiversity pattern in these two site pairs. Firstly, these two groves and their control sites are in closer proximity to the nearest village than is the case for the other sites. This could have led to more intense anthropogenic influence or, alternatively, it might have increased the effectiveness of the protection associated with religious prohibitions (Frosch et al., 2016). Secondly, they are located on very steep slopes, so these groves would require strict protection to fulfil the role of erosion or landslide control. Looking closely at each sacred grove, it becomes apparent that its current status has been individually shaped by its history. For example, despite a long history of protection, one of the conifer groves is the forest of Konitsa (4S) was heavily logged for timber and fuel wood in the 1940s, during the Second World War and the following Greek Civil War. Subsequently, in 1953, the municipality decided to manage the forest by removing mature trees in an effort to raise funds for enforcing its protection, particularly of its most degraded parts. Our review of the management history of the eight sacred groves also reveals site-specific variation in the enforcement of restrictions on tree cutting or livestock grazing,

386 which are likely to have influenced considerably the habitat properties and, hence,
387 conservation capacity.

388 Land abandonment is another driving force in the evolution of the landscapes of this area. In
389 the postwar period, as agriculture in Western Europe entered a productivity-orientated phase,
390 agricultural change in the study area coincided with decline of agricultural activity or simply
391 of its abandonment. Crop fields disappeared and grasslands gradually developed into
392 shrublands and forests due to a decrease in animal grazing and subsequent natural succession.
393 An exception to that is Konitsa, where the surrounding fertile lowlands remain agricultural to
394 this day (Zomeni et al., 2008). This homogenization of the landscape may explain the
395 differences between sacred and control sites being only marginal. Photos from 1945 and 2007
396 (Fig. H.1) reveal a changing forest landscape with the forest areas around the groves most
397 often expanding. Thus, a possible hypothesis is that the sacred groves acted as nuclei of
398 expansion and dispersal of biodiversity into newly regenerated forest areas.

399 Because sacred groves along the mountainsides of Epirus were established for their benefits
400 in terms of cultural and religious beliefs, hill-slope protection, recreation or even scenery
401 (visual amenity), rather than for biodiversity conservation *per se*, they can be described as
402 suffering from a kind of "rocks and ice syndrome" (Terborgh, 1999). Biodiversity
403 conservation was not the priority in delimiting these areas; this has emerged as a secondary
404 benefit. For that reason, the sites chosen for sacred status were not selected according to
405 conservation criteria. This is especially the case with respect to their size. Size is a major
406 factor limiting conservation capacity (Halpern, 2003; Ramesh et al., 2016), both with respect
407 to the number of species that can be supported in the long-term and in the length of time an
408 extinction debt can be sustained following isolation (Fig. 4). However, people establishing
409 sacred groves might settle for much smaller areas than are necessary in conservation terms, as
410 can be seen at a global scale in Fig 4.

411 No size dependence was observed for the diversity of sacred groves. This was initially
412 surprising, given the expected dependence of species richness and relaxation time on area.
413 However, as the actual sampling area (given any taxonomic group) is the same in each site
414 we expect this to increase only weakly with site area (Phillips et al., 2017). Furthermore, we
415 should not think of these groves as islands of forest in a landscape of cultivation. The groves
416 have always existed in a matrix of habitable or partially-habitable landscape, so for this
417 reason also, it is not so surprising that measurements of diversity fail to show the limiting

418   effect of size expected from Eq. 1. Finally, consistent with historical and photographic

419   evidence, the area of groves is not constant. Most have expanded since 1945 while some were

420   not isolated even in 1945. Also, the variability of areas is not so great (Fig 4a), so that area

421   dependence is not easily detectable if statistical power is low. Thus, while Eqs (1-3), based on

422   isolated fixed-area island models, can illuminate our understanding of conservation capacity

423   and relaxation time, they must be used in conjunction with historical and landscape

424   information when their basic assumptions are not met.

425   These results show a conservation benefit of SNS, which is variable amongst taxa and is

426   affected by the type of grove and by management history. Other SNS in Epirus or elsewhere

427   are likely to behave similarly, particularly if they are of similar size. Thus, in the wider

428   context, if SNS are to play a role in modern conservation, these factors must be carefully

429   assessed. Extension of the analyses reported here should prioritize a landscape-scale

430   assessment of the relative fragmentation of the different sacred groves and control sites, and

431   the extent to which this explains the variation in their species composition and diversity

432   (Echeverría et al., 2007; Daye and Healey, 2015). A fuller knowledge of the historical context

433   can help in this, especially regarding changes in management regime. The issue of vegetation

434   type should be also addressed so as to clarify if it really plays an important role in

435   conservation efficiency.

436   The sacred groves studied here are small in size and have been affected by changing degrees

437   of protection and management throughout their history. Many of them could not function as a

438   reserves or conservation areas by themselves. However, following another modern paradigm,

439   that of the European Natura 2000 system (Official Journal of the European Union, 2011), a

440   network of protected areas existing in an agricultural matrix (following the "countryside

441   SAR" principle) (Pereira et al., 2014) offers an alternative approach. If SNS were

442   incorporated into wider parks or networks, the small conservation advantage that we

443   observed here could become more important. Moreover, a conservation network based

444   around such areas might gain local recognition more readily than a park or network

445   developed on a purely scientific basis. As a large proportion of SNS are small, this approach

446   is likely to be important globally.

688
691 **Figure 1** Identified sacred groves (circles) in the broad area of Zagori and Konitsa. For the
692 current study, biodiversity was measured in eight of these sacred groves (green circles) and in
693 eight corresponding control sites (squares). Shown in the inset is the location of the Epirus
694 study area in Greece. Red lines denote major roads.

695
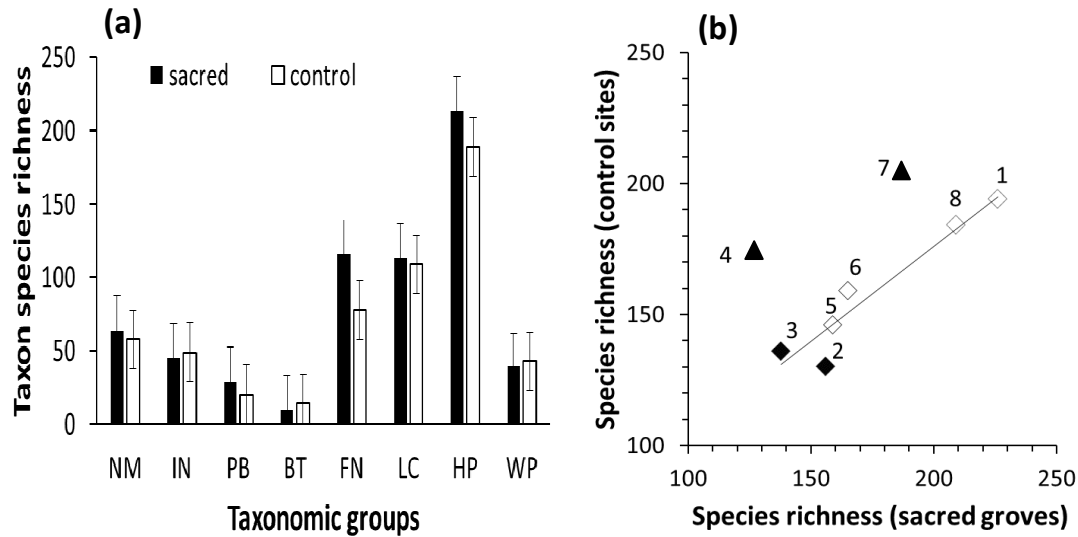

Figure 2 Representations of biodiversity in the sacred and control sites for various taxonomic groups: **(a)** Total species richness (genus richness for nematodes) in each group of species across all eight sacred groves and their respective control sites (with mean and standard error bars). Taxonomic groups are: NM, nematodes; IN, insects; PB, passerine birds; BT, bats; FN, fungi; LC, lichens; HP, herbaceous plants; WP, woody plants. (**b**) Scatterplot of species richness recorded in sacred groves and their respective control sites. The fitted line ($y=0.727x+30.56$, $R^2 = 0.912$) was calculated after the two pairs of sites dominated by conifers (4 and 7) were excluded. Open diamonds are deciduous broadleaved sites, closed diamonds evergreen broadleaved sites and closed triangles coniferous sites.

23
Figure 3 Species turnover measured as the beta diversity between the local scale (sites) and global scale (union of sites): (**a**) Whittaker index and (**b**) N^* index for the sets of eight sacred groves (black) and respective control sites (gray), by taxonomic group (NM, nematodes; IN, insects; PB, passerine birds; BT, bats; FN, fungi; LC, lichens; HP, herbaceous plants; WP, woody plants) with error bars corresponding to the standard deviation of the species accumulation curve used to estimate the N^* index. In the case of nematodes, genus turnover is shown.

726

727
Figure 4 (a) Histogram of area for 126 SNS: 22 mapped in Epirus and 104 found in our literature search. Superimposed on this is the expected half-life of species loss following habitat isolation using Eq. 3 for all taxonomic groups except fungi and lichens for areas ranging from 0.01 hectare to 100,000 km^2. The taxonomic group name appears below the line except for nematodes and woody plants for which it is above the line. The sizes of the eight sacred groves of Epirus in this study are shown as black dots just above the horizontal axis. **(b)** Histogram of area for the national parks in Greece (light blue), Great Britain (red) and the USA (dark blue). The main divisions (powers of 10) in the horizontal axis are the same for both panels.

737

738 **Table 1.** Location, area and vegetation type of the eight sacred groves (S) and their respective
739 control sites (C). For vegetation type, D = deciduous broadleaf, E = evergreen broadleaf, C =
740 coniferous forests.

741

Associated village	Vegetation type	Sacred groves		Control sites	
		Code	Area (ha)	Code	Area (ha)
Aidonohori	D	1S	19.8	1C	16.24

742

Appendix A – Selection of sacred groves, control sites and sampling points

751 *Sacred sites*

752 We identified sacred grove sites across the landscape based on archival and ethnographic
753 fieldwork. We further identified and mapped the borderline of these groves using ortho-
754 rectified aerial photographs from the year 1945, which is the oldest complete set of aerial
755 photographs of the area. From these identified sacred groves, eight were selected on the basis
756 of a number of criteria. Firstly, we excluded those less than 3.5 hectares in size, as estimated
757 for 1945, so as to secure at least one permanent bird observation point of 100 m radius (see
758 Appendix B) in each grove. Secondly, we excluded all sites for which there was evidence of
759 substantive felling of trees during the last 60 years, according to the Forestry Department
760 management plans and records or earlier ethnographic or field research. To the remaining
761 sites, we applied the criteria of a minimum threshold of 70% current tree cover and lack of
762 degradation, based on recent ethnographic and field data. From the initial shortlist of sites, a
763 stratified set of sacred groves was selected so as to cover a range of cultural diversity
764 (cultural units, ritual praxes and management regimes) according to ethnographic data (See
765 Appendix E). Where possible (all criteria being satisfied), groves closer to roads were chosen
766 so as to reduce field work and allow more time for sampling. The final set of sacred groves
767 that were selected was limited to eight because of time constraints.

768

769 Fig A1. View from inside three sacred groves of different types: (left) Elafotopos, a broadleaved evergreen
770 forest (2S), (middle) Molista, a coniferous forest (7S), and (right) Aidonochori, a deciduous forest (1S). (Photos
771 K. Stara 2015)

772

773 *Control sites*

774 Since our main hypotheses concern biodiversity, we define a control site for each sacred
775 grove so as to assess the biodiversity difference relative to a non-sacred, reference forest.
776 This approach has been used widely in similar studies of biodiversity comparisons (Wortley
777 et al. 2013, Derhé et al. 2016). Here, the selection priority is to find a non-sacred forest for
778 which the environmental factors are as close as possible to the sacred grove. Thus, for each of
779 the eight sacred groves, we identified the best matched control site (without sacred status but
780 with similar site environment and vegetation characteristics) according to a series of criteria:
781 (a) the site had to be close to the respective sacred site (less than 4 km), (b) its area should be

782 as large or larger than the respective sacred site, (c) tree cover in it should be no less than
783 70%, (d) it should be of the same vegetation type (dominated by coniferous, evergreen
784 broadleaved or deciduous broadleaved trees) as the sacred grove, (e) it should have the same
785 geological bedrock, and also (f) similar slope and aspect. Selection was based on the analysis
786 of ortho-rectified aerial photos from 2007, existing forest vegetation maps, digitized
787 geological maps of 1:5000 scale, and the Google Earth digital elevation model, supplemented
788 by observations during field visits. Their boundaries were defined using all of the above
789 criteria. Control sites were usually part of larger contiguous woodland areas and except for
790 one, they were larger in area than the sacred sites.

791

792 Fig A2. View from the outside of two sacred groves of different types: (left) Molista, a coniferous forest (7S)
793 lies behind slope above village, and (right) the evergreen broadleaved grove of Kato Pedina (3S) rises upwards
794 to the right along the slope above the village. See also Appendix H. (Photos K. Stara 2015)

795 *Sampling points*

796 Inside each sacred site and in each corresponding control site, a set of points was chosen by
797 random placement. These points were subject to the additional constraints that they should be
798 located at least 100 m from the woodland edge and separated from any other by at least 300
799 m. These criteria define a maximum number of independent sample plots that can fit in each
800 site. A heuristic algorithm [Generate Random Points, provided by the online software
801 ‘Geospatial Modelling Environment’ (www.spatialecology.com)] was employed to provide
802 the sequence of potential sampling points for each taxon. A common sequence of random
803 points was generated for each site and provided to all the teams working on different
804 taxonomic groups. However, the teams were not constrained to use the same points. For each
805 taxonomic group, the same sampling effort was used in all sites and the total number of
806 species that were found in the site was recorded.

807

808 **Appendix B – Sampling protocols**

809 *Nematodes*

810 Four sampling points were chosen at each site (sacred and control) and at each a plot of 100
811 m^2 was established. In each plot, a composite soil sample of five soil cores, 3 cm in diameter

812   and 12 cm in depth, was collected, so that four composite samples were taken from each site.
813   In all cases, the litter layer was removed before sampling. Nematodes were extracted from
814   200 cm^3 of each composite soil sample. For extraction, the modified Cobb's sieving and
815   decanting method (S'Jacob and van Bezooijen, 1984) was employed. After counting total
816   abundance of nematodes, samples were fixed with 4% formaldehyde solution. From each
817   sample, 150 nematodes were selected and identified to the genus level using an identification
818   key (Bongers, 1994). In cases where the number of specimens of a sample was less than 150,
819   we identified them all.

820   *Insects*

821   One sampling point was chosen at each site. Insect sampling was conducted using a modified
822   Pollard sampling scheme (Caldasa and Robbins, 2003), following transects in four directions
823   (N, S, E, W) of 200 m, with a width of 10 m on each side of the center line, lasting exactly 45
824   minutes. Sites were visited twice (early summer 2013 and late summer 2014) for five days
825   each time, in order to include species that appear in different periods during the year, while
826   the order at which sites were sampled differed each time, so as to avoid a bias induced by the
827   specific time of the day. Flying adult insects were collected in nets, whereas soil dwelling and
828   wood-boring adult insects were retrieved with the help of a knife and a tweezer. Specimens
829   were then put into plastic bags and were given a label that described the site, the time and the
830   number of individuals observed for each species. Identification was conducted at the
831   Laboratory of Forest Entomology (Forest Research Institute - HAO Demeter, Greece) using
832   the appropriate morphological keys for each insect order.

833   *Passerine birds*

834   One sampling point was chosen at each site. Point counts of a fixed radius of 100 m were
835   carried out, recording all bird species observed or identified from their calls and breeding
836   songs for a fixed time period of 10 minutes. One point-count was conducted per site, at the
837   same fixed point, in early morning (from 30 min before dawn and for a duration of 3 h) on
838   two dates, in early and late spring (with the interval between replicates being less than 30
839   days). Breeding songs were considered to indicate a pair of birds, whereas all other
840   observations indicated one individual. The sum of individuals that were recorded on the two
841   sampling dates, in each site, were taken as the measure of abundance in the analysis.

842   *Bats*

843   One sampling point was chosen at each site. Starting from there, another four sampling points
844   were selected on a line with an approximate distance of 100 m between them. Echolocation
845   calls of bats were recorded at each point for 15 minutes as well as between points (while
846   walking from one point to the next), using the ultrasound receiver Batcorder (ecoObs).
847   Recordings started half an hour after sunset and lasted approximately one and a half hours in
848   each site. Sampling was conducted from mid to late summer and was repeated twice in each
849   site, in 2013 and 2014. Calls were analyzed and species were identified by use of the
850   ultrasound analysis software bcAnalyze v.2 (ecoObs).

Fungi

Sampling was conducted at eight sampling points within each sacred and control site. At each point, a plot of 200 m² was clearly marked along its edges and carefully examined for fungal carpophores. The area was visited twice during the year: in autumn, when most Basidiomycetes fruit, and again in spring in order to observe the fruiting Ascomycetes. Sampling was thus carried out four times in each of the 16 sites: autumn 2013, spring and autumn 2014 and autumn 2015. The exact timing of the visits relied on the information given by local collaborators about the occurrence of fruiting. Carpophores on all substrates (soil, leaf litter, dead wood) were sampled. Their identification was based on their macroscopic features in the field. Specimens of each species were counted and recorded. Specimens whose identification was in doubt were kept in portable coolers and taken to the Laboratory of Forest Pathology & Mycology (Forest Research Institute - HAO Demeter, Greece) for further laboratory examination and verification.

Lichens

In each site, one sampling point was chosen as the centroid of a 250 m^2 sample plot. Lichen sampling was carried out on tree trunks up to 2 m above ground, on five individuals of each tree species present in the plot. The sampling followed a random time- and species recovery-constrained strategy: on the set of sampled trees, all crustose, foliose or fruticose species observed were collected until no additional species could be detected. All collecting sites were visited once. The identification of the lichen material was carried out using stereo- (Zeiss Stemi) and light-microscopes (Zeiss Axioscope). Standard chemical spot tests, based on potassium hydroxide, bleach, iodine and para-phenylenediamine, and thin layer chromatography (Orange et al., 2001) were applied, and results were compared with those from literature (Clauzade and Roux, 1985; Nimis, 1987; Purvis et al., 1992; Wirth, 1995). Specimens are stored at the GZU Herbarium of the Institute of Plant Science, Karl-Franzens University of Graz (Austria).

Herbaceous and Woody Plants

In each site, two sampling points were selected. At each, a plot of 250 m^2 was set up. Within these plots, every vascular plant, whether a seed plant (Spermatophyta) or a fern (Pteridophyta), was identified to species level and recorded. Species were further divided into herbaceous and woody plants.

Appendix C - Species richness and its analysis

The location of the eight selected sacred groves of Konitsa and Zagori, in Epirus, northwestern Greece, and of their matching control sites are presented in Table C.1. Given are for each site (sacred grove or control) the number of species that were recorded for each of the eight taxonomic groups examined per site and overall.

887   A generalized linear regression model was built to test the effect of site area (area containing
888   the sampling locations within each site), site type (sacred or control) and vegetation type
889   (dominated by coniferous, evergreen broadleaved or deciduous broadleaved trees) on the total
890   species richness (*S*) and on the species richness within each taxonomic group (for nematodes
891   this was genus richness). The model used is *S ~ area + type + vegetation type + area*:*type*,
892   with a Poisson response and a logarithmic link function. The results are summarized in Table
893   C.2. The significance of each predictor variable is judged on a 5% significance level.

Appendix D - Ordination analysis

To visualize the difference in composition between sites, multidimensional scaling analysis based on Bray-Curtis dissimilarity was conducted for each taxon, separately, and for all taxa combined. The analysis was implemented in R 3.2.3 (R Core Team, 2015) using function *isoMDS* of the MASS package (Venables and Ripley, 2002) and function *vegdist* of the VEGAN package (Oksanen et al., 2016).

For herbaceous and woody plant species, ordination showed a surprising lack of differentiation in floristic composition between the three vegetation types corresponding to different topographic positions (Fig. D.1). This is possibly due to the fact that we have only presence counts for these taxonomic groups. For the other species, patterns of species composition amongst sites varied notably by taxonomic group. For lichens, insects and bats, there was no clear pattern, with much overlap amongst the pairs and the vegetation types. For passerine birds, there was a clear distinction amongst the three vegetation types, but the two sites within each pair were not closely clustered. Notably, for passerine birds there is a separation between sacred groves and control sites. For the remaining two taxonomic groups, the conifer-dominated sites were distinct from the broadleaf tree-dominated ones, but whereas for the fungi the two sites within each pair were quite well clustered, for the nematodes they tended to be split. For all species combined, there is a clear distinction in the species composition of the three vegetation types and for the majority of the eight pairs (Fig. D.2). However, the ordination analyses did not reveal any consistent differences in

928 composition between the two types of sites (sacred groves and control) for the individual
929 groups of species or for all species combined.
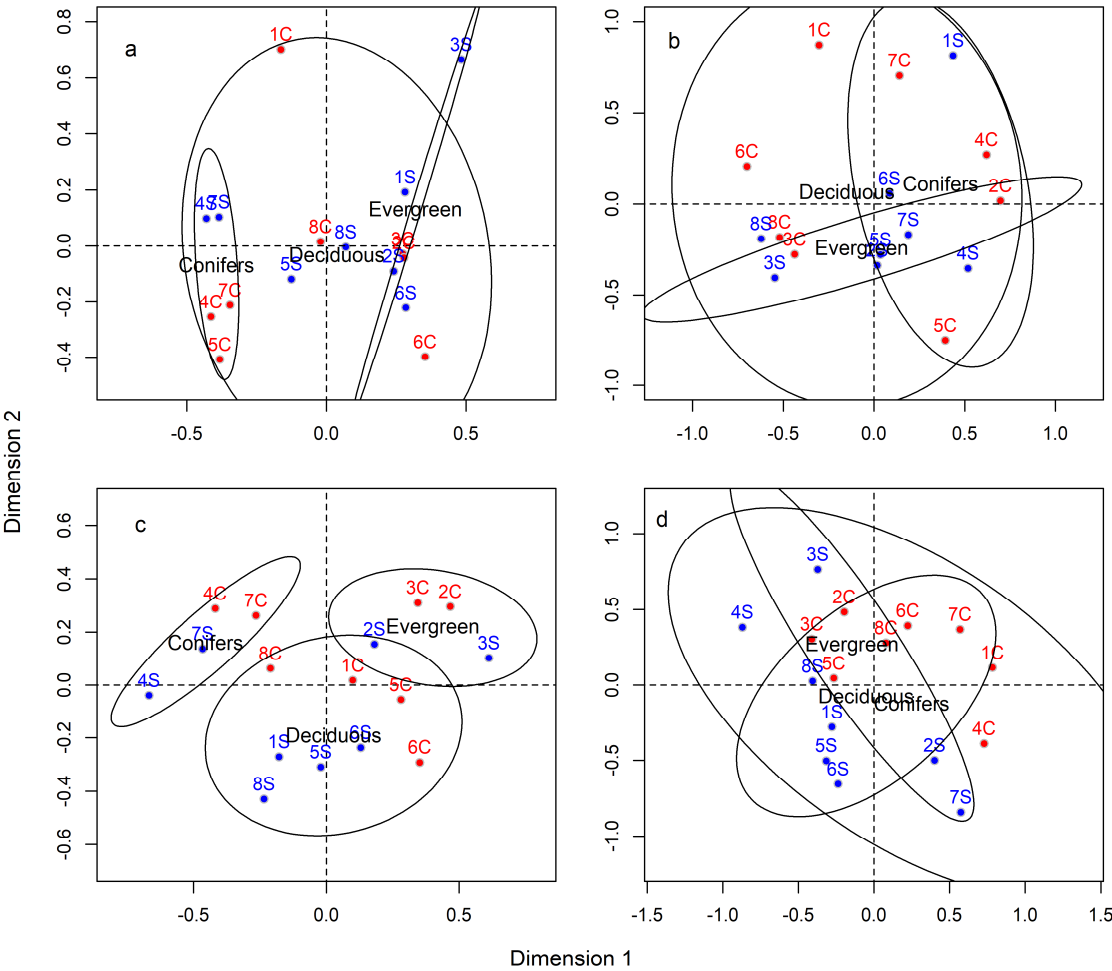

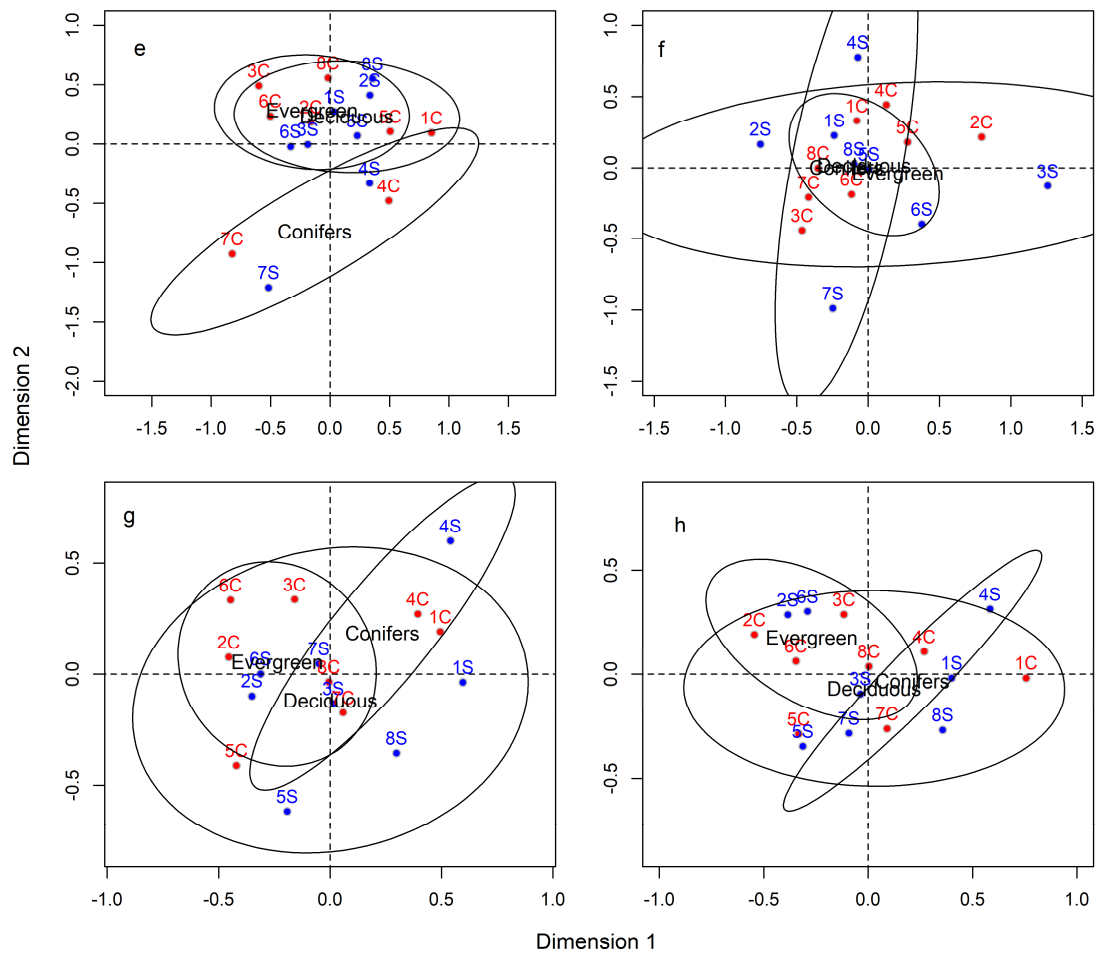

Figure D.1. Ordination of sacred groves (S) and respective control sites (C) using multidimensional scaling with the Bray-Curtis dissimilarity index as a measure of the distance between sites for (**a**) nematodes, (**b**) insects, (**c**) passerine birds, (**d**) bats, (**e**) fungi, (**f**) lichens, (**g**) herbaceous plants, (**h**) woody plants. Ellipses define 90% intervals of the distribution of scores within the three vegetation types dominated by different tree types (C, coniferous; E, evergreen broadleaved; D, deciduous broadleaved). The analysis was implemented in R using function *isoMDS* in the MASS package.
Figure D.2. Ordination of sacred groves (S) and respective control sites (C) using multidimensional scaling with the Bray-Curtis dissimilarity index as a measure of the distance between sites. Data from all taxa were reduced to presence-only before carrying out the analysis. Ellipses define 90% intervals of the distribution of scores within the three vegetation types dominated by different tree types (coniferous, evergreen broadleaved and deciduous broadleaved). The analysis was implemented in R using function *isoMDS* in the MASS package.

951 **Appendix E – SCI species**

952 **Table E.1.** Species of Community Interest (SCI) identified in each sacred grove and
953 respective control site of this study. Of the 8 taxa investigated, SCI species were identified
954 only for bats, insects, passerine birds (Passer.), herbaceous plants (P-herb) and woody plants
955 (P-Wood), as nematodes were identified at the genus level and in some cases also lichens and
956 fungi.

Appendix G – Ethnographic Research

Methods

Ethnographic study of the sacred groves of Epirus aiming to describe people's valuation and perception of different tree species and to identify the sacred natural sites and their emblematic trees (Stara et al., 2015) started in 2005, involving initially 23 villages in Zagori. Work resumed in 2012 and covered the rest of Zagori and the adjacent area of Konitsa.

975 Research for this study of the archives of municipalities, the Forestry Service and the Church,
976 and of local libraries targeted at finding references to the sacred groves and their history, in
977 general, and of those selected for the study, in particular. Ethnographic research involved
978 interviews with local people. They were asked about their community's sacred groves, the
979 reasons for their maintenance, also about their history and the ritual activities, the
980 supernatural guardians, acceptable and non-acceptable uses, and stories or taboos about
981 trespassing in the groves (Stara et al., 2016).

982 *Management regimes in the sacred groves of Epirus*

983 The groves appear either in the form of protective forests above or close to villages or as
984 groups of veteran trees that accompany outlying churches ("xoklissia") or icon stands
985 ("eikonismata", shrines comprising boxes containing icons and an oil lamp that remains lit
986 most evenings; Stewart, 1993; Nixon, 2006) retaining a protection value through association
987 with various Orthodox saints (Politis, 1904; Kyriakidou-Nestoros, 1989). Management
988 regimes in the sacred groves of Epirus vary from strict protection to controlled management.
989 These regimes are site-dependent and related to the specific reasons for which these groves
990 were established and maintained, to the type of religious dedication, the perceived personality
991 of the protector saint or saints, historical circumstances and community needs. When a
992 church with a sacred grove was founded on the epiphany of the divine, then the protection
993 was strict. For example, for the grove in Vovoussa in East Zagori, dedicated to the saint Agia
994 Paraskevi, local people argue that Agia Paraskevi herself chose the exact point, where the
995 church should be built, through various manifestations, such as repeatedly moving her icon
996 there. The local cult remains very much alive today linked to that grove and all harvests (e.g.
997 from hunting, collecting honey from wild bee hives, plants, mushrooms, dead wood etc.) are
998 still strictly prohibited (Stara et al., 2016). Strict regimes also tended to prevail for protective
999 forests on very steep slopes (e.g. at Molista, site 7S; Table S1, Fig S3). In contrast, the regime
1000 in some groves is much more relaxed (e.g. at Mazi, 5S; Table S1, Fig. S3); for instance,
1001 grazing is allowed without restrictions during certain time periods. Harvesting of branches
1002 ("shredding") of evergreen tree species during harsh winters (for fuelwood or animal fodder)
1003 was allowed occasionally by church and community councils, whereas shredding of
1004 deciduous tree species during early spring was always considered a trespass. In extreme
1005 cases, controlled management might permit timber harvesting for necessary public works.
1006 Some tolerance of breaking these rules was extended to members of lower social strata.
1007 Finally, collective trespassing could be allowed in abnormal situations. For example, in times
1008 of war or during festivals that are characterized by the ceremonial reversal of social order, the
1009 collection of dead wood and flammable branches of shrubs for use might be allowed (e.g. at
1010 Christmas or for carnival bonfires). Several hamlets in the area were consolidated during the
1011 16th to 17th century forming the present villages. Where settlements are abandoned, their
1012 associated sacred groves are often gradually neglected and only mature trees in the vicinity of
1013 the church itself are protected (Stara et al., 2016).

1014

Excommunication

1016   Excommunication is the exclusion of a person from the Church and the deprival of its
1017   mysteries. In the Orthodox Church, it is the heaviest punishment that can be imposed on a
1018   Christian. From the later Byzantine period, and particularly under the Ottoman rule,
1019   excommunication was commonly employed for offenses of economic or social character, as
1020   are cases of theft, rape, livestock stealing, defamation, trespassing etc. It was also used as a
1021   threat in order to protect trees and other natural resources from trespassing and interference
1022   (Mihailaris, 2004; Stara et al., 2012).

1023

1024   **Appendix H – Aerial Photos of sacred groves in 1945 and 2007**

1025   The exact borders of the sacred groves studied were identified and mapped using ortho-
1026   rectified aerial photographs from the year 1945, the oldest complete set of aerial photographs
1027   of the area (source: Hellenic Military Geographical Service, digital aerial photo 1945 -
1028   orthorectified) and compared with the most recent set of 2007 (Hellenic Cartographic and
1029   Cadastral Organisation, digital orthorectified image 2007). The scale for all photographs is
1030   1:7,500 except for the site 4S (Konitsa) for which it is 1:20,000.

1031   These photos reveal a changing forest landscape, with the forest areas around the groves
1032   often expanding. Sites 1S, 4S, 5S and 7S were not isolated from the surrounding forest areas
1033   even in 1945.

1034   Sites 1S and 5S show little net change in cover but exhibit a pattern of patchy increase or
1035   decrease in tree cover within the sacred grove. The area surrounding site 5S changed in
1036   vegetation structure, from a dense scrubland to a young forest as grazing by goats decreased.

1037   In sites 2S, 4S and 7S, forest cover remained high within the sacred grove but with
1038   substantial changes in the surrounding matrix. Whereas the sacred groves in 1945 were
1039   largely isolated (surrounded mainly by rangelands, scrublands or wood-pastures with
1040   minimum tree cover), by 2007, much of this surrounding matrix was covered by trees. This is
1041   predominantly because of the cessation of grazing that allowed the regrowth of forests. In the
1042   case of conifer forests (sites 4S, 7S), trees in the sacred groves could have been an important
1043   seed source, while for the other types, existing shrubs (e.g. around site 2S) can take tree form
1044   once grazing stops.

1045   Sites 3S and 6S show a similar trend of a large increase in tree cover between the two dates,
1046   both inside the sacred grove and in the surrounding matrix.

1047   Around site 8S, there is substantial increase in tree cover in the surrounding matrix, with just
1048   patchy changes in tree cover inside the sacred grove, as grazing (goats, sheep and cows) is
1049   still active forming an open extensive wood pasture characterized by scattered trees and
1050   scrubs.
