Conventional microscope objective lenses are diffraction limited; they cannot resolve subdiffraction features of size smaller than 250-300 nm under white lighting condition. New innovations are required to overcome such limit. In this paper, we propose and demonstrate a new superlensing objective lens which possesses a resolution of 100 nm, offering two times resolution improvement over conventional objectives. This is accomplished by integrating a conventional microscope objective lens with a superlensing microsphere lens using a customized lens adaptor. The new objective lens was successfully demonstrated for label-free super-resolution imaging of 100 nm features in engineering and biological samples, including a Blu-ray disc sample and adenoviruses. Our work opens a new door to develop a generic optical superlens, which may transform the field of optical microscopy and imaging.

1. INTRODUCTION

Objective lens is the core element of an optical microscope, whose resolution is limited by the classical diffraction law as first formulated by the German physicist Ernst Abbe in 1873: The minimum distance, d, between two structural elements to be imaged as two objects instead of one is given by d = λ/(2NA), where λ is the wavelength of light and NA is the numerical aperture of the objective lens [1]. The physical root stems from the loss of exponentially-decaying evanescent waves in the far field that carry high spatial frequency subwavelength information of an object [2].

The development of Near-field Scanning Optical Microscope (NSOM) opens the door to super-resolution research. It uses a tiny tip positioned close to an object's surface to collect evanescent waves in near-field [3]. Scanning the sample generates a super-resolution image whose resolution is determined by tip size instead of wavelength. Since the late 1990s, owing to the arising of metamaterials, plasmonics, and plasmonics, the field of super-resolution research grows extremely rapidly. A variety of super-resolution techniques were developed, including for example Pendry-Veselago superlens [2, 4], optical superoscillatory lens [5], time-reversal imaging [6], Maxwell fisheye [7], scattering lens [8], and most famously, the super-resolution fluorescence microscopy techniques [9–11] which won the 2014 Nobel Prize. However, none of these techniques would operate under white lighting sources, e.g. the conventional Halogen lamps or recent white LEDs, whose radiation covers a broadband electromagnetic spectrum. Monochromatic lasers are required. The solution to white light super-resolution appears in 2011, when we first reported that microsphere can work as a superlens under white lights and achieve a resolution between 50-100 nm [12–14]. The super-resolution arises from microsphere’s ability to focus light beyond diffraction limit, a phenomenon known as ‘photonic nanojet’ [15, 16], and near-field collection of evanescent waves by the microspheres in contacting with imaged objects. This technique is label-free and has been advanced since by a number of groups across the world, including for example the developments of confocal microscope nanoscopy [14, 17], solid immersion microscope nanoscopy [18, 19], microfiber nanoscopy [20], subsurface nano-imaging [21, 22], and new designs of microsphere superlens [23, 24]. Very recently, we demonstrated new superlens made from high-index nanobeads [25] and create the world’s first biological superlens using spider silks [26]. For better understanding of the field, please refer to our recent review article [14].

The imaging window of a microsphere lens is often very small, typically a few micrometers only. This requires a scanning operation of the microsphere superlens to generate a complete image of a sample. There are a few demonstrations in the literature. Krivitsk et al. attached a fine glass micropipette to the microsphere lens to scan the particle [27]. Li et al. designed a ‘swimming lens’ technique in which the microsphere lens was propelled and scanned across the sample...
surface by chemical reaction force in a liquid [28]. We proposed a coverslip superlens by encapsulating high-index microspheres (BaTiO₃ or TiO₂) inside a transparent host material (such as PMMA and PDMS)[29]. The microsphere was completely immersed inside the encapsulation material with its bottom touching the coverslip surface (see Fig. 1a side view). This concept was also explored extensively by Darafsheh and Astratov et al. in the US [18, 30, 31]. The coverslip superlens can be manually manipulated in a way similar to classical coverslip, offering the freedom to position particle lens at desired location. Scanning of microsphere superlens, however, requires synchronization with microscope objective for full super-resolution image construction. This is difficult to achieve with existing design of coverslip superlens which is separated from objective lens. In this paper, we propose an improved design which solves the synchronization problem between coverslip superlens and objective lens. The idea is simple yet effective, using a custom-made lens adaptor to integrate these two lenses to form a superlensing microscope objective lens.

2. SUPERLENSING MICROSCOPE OBJECTIVE

A coverslip superlens (Fig.1a) was bonded to the bottom end of the adaptor using high-adhesive glue. This results in an integrated objective lens consisting of conventional OB and a Coverslip Microsphere Superlens (CMS). The imaging resolution will be determined by the coverslip superlens while the conventional objective lens provides necessary condition for illumination. The obtained superlensing lens can be easily fitted to any existing conventional microscopes; in this study, we used two brands of optical microscopes to prove the lens’s flexibility (Olympus BX60 and a low-cost ICM100 microscope) in usage.

The scanning was performed using a high-resolution nano-stage (model PI P-611.3 Nanocube), with 1 nm resolution in XYZ direction, travel range 100 μm. Samples (Blu-ray disc, semiconductor chip, virus on glass slider) were firmly bonded to the nano-stage using high-strength double-sided sticking tape. In experiments, the superlensing objective lens was kept static and the underlying nano-stage moved and scanned the samples across the objective lens. The imaging process was video recorded using a high-resolution camera (ToupCam UCMOS 14000KPA). The video was then analysed and frames were used to generate a stitched image of the sample. The focusing properties of developed superlens were analysed using classical Mie theory.

3. EXPERIMENTS

A. Static Imaging

The superlensing objective lens was carefully adjusted to maximum imaging contrast and image quality. The main adjustments include the followings: (1) the lens adaptor was adjusted so that the top objective lens will pick up virtual image generated by the bottom coverslip microsphere superlens. (2) Light illumination angle was adjusted, roughly an angle between 10-40 degrees will produce enhancement in image quality, because the magnification factor is increasing with incident angles and there is a compromise between image quality and magnification factor [26]. Best imaging resolution is obtained in contacting mode where lens and samples contact with each other. The resolution was found decreasing rapidly when lens moved away from the sample surface, at about the wavelength distance (~600 nm) away the super-resolution was completely lost (due to loss of evanescent wave contribution) which indicates the near-field nature of the technique.

In the contacting mode, we carried out super-resolution imaging of several different samples, including Blu-ray disc with 100nm/200nm features and adenosviruses (replication deficient human adenovirus serotype 5 vector) with size about 90-100 nm. Noting superlensing objective lens in these tests could be slightly different from each other, with an aim of demonstrating the ability to achieve super-resolution with different lens configurations. As previously mentioned, the overall resolution is determined by Coverslip Microsphere Superlens (CMS) which consists of BaTiO₃ microsphere (3-80 μm) inside PDMS sheet. Figures 2(a-c) demonstrate Blu-ray disc imaging using the developed superlensing objectives. In Fig. 2(a), the SEM image reveals that the disk consists of 200 nm gratings separated 100 nm away. Figs. 2(b-c) show the images obtained using Olympus BX60 microscope equipped with developed superlensing objective lenses with the following parameters: Fig. 2(b) with OB (100x, NA0.90) + CMS (67 μm BaTiO₃ in PDMS) and Fig. 2(c) with OB (100x, NA0.90) + CMS (22 μm BaTiO₃ in PDMS).

As can be seen, both lenses can clearly resolve the 100 nm features, which is beyond the classical diffraction limit of 300 nm. The smaller diameter BaTiO₃ superlens in Fig. 2(c) offers a larger magnification factor (M~6x) over the larger sized BaTiO₃ superlens.
Supplementary video 1) lens during scanning. This is due to the virus particles not imaging of virus samples, since the virus particles were dragged by the sample contacting requirements, we evaluated scanning imaging of different samples, including the adenovirus samples. However, due to lens-sample contacting requirements, we had some difficulty in scanning imaging of virus samples, since the virus particles were dragged by the lens during scanning. This is due to the virus particles not being well fixed onto the glass slides. This may not be the case for cell samples which could be immobilized on glass slides and is the plan of our next step experiments. In this study, scanning imaging was performed with a well-structured semiconductor IC chip and Blu-ray disk sample to demonstrate the feasibility of scanning imaging using developed superlens imaging, artificial images are always an issue and one should pay particular attention to it. The artificial images can be excluded by rotating the imaging samples.

Let’s turn our eye on another sample, the adenovirus sample. These virus particles are nearly spherical in shape with diameter around 90-100 nm (Fig. 2d), and they are sub-diffraction-limited and difficult to be observed using conventional microscopes. Figure 2(e) shows a super-resolution image obtained using a superlens objective lens formed by 80x, NA0.90 objective and 70 µm BaTiO₃ microsphere. The virus particles are aggregated in clusters in our sample, but it was possible to isolate them by zooming in the image. The magnified particle size is about 200 nm in Fig. 2(f), which means the real virus size is around 100 nm since the 70-µm BaTiO₃ superlens offers a magnification factor around 2 under the experimental condition. Compared to Fig. 2(b), here the central zone doesn't have a bright spot due to reflection by underlying substrate, this is because virus particles are deposited on a glass slider which is transparent and has much less reflection compared to a Blu-ray disc.

B. Scanning Imaging and Image Stitching

In our superlens objective lens, the microsphere superlens is synchronized with objective lens. During the scanning operation, both parts of the lens will move together simultaneously, and their relative position is kept constant. This is beneficial to scanning imaging since it ensures that the same particle lens is used in imaging. It is also possible to have multiple particle lenses in parallel for simultaneous scanning imaging. In experiments, we evaluated scanning imaging of different samples, including the adenovirus samples. However, due to lens-sample contacting requirements, we had some difficulty in scanning imaging of virus samples, since the virus particles were dragged by the lens during scanning. This is due to the virus particles not being well

Light interaction with spherical particles can be simulated using the classical Mie theory. Figure 4 shows examples of calculated electric field intensity $|E|^2$ distribution across cross-sectional plane of an 18 µm and a 67 µm BaTiO$_3$ microsphere (n=1.90) embedded in PDMS (n=1.40) under different illumination wavelengths, covering 400 nm to 700 nm spectrum range of a typical white lighting source. The corresponding size parameter for each case, defined as $\alpha=\pi D/\lambda$, where D is the particle diameter and $\lambda$ the wavelength, was also indicated in the figure. A video was provided in the Supplementary (video 2) offering a systematic view of the evolution of field distribution for size parameters $0.1 \leq \alpha \leq 0.628$, with step accuracy of $\Delta \alpha=0.1$. From Fig. 4 we can see, besides the well-known photonic nanojet focusing modes by microspheres (Figs.4a, 4c, 4d, 4f), strong internal focusing modes featuring hugely enhanced intensity peaks inside the particle could be excited at particular wavelengths (Figs. 4b, 4e). All these modes will play a role in super-resolution image formation.

The imaging sample in contact with microsphere is illuminated by the microsphere lens; super-resolution arises from the strong near-field interaction between the microsphere lens and underlying nano-objects, which leads to the conversion of surface-bounded high spatial frequency evanescent waves into propagating waves [14, 32]. Such interaction process is quite complex and is out of the scope of Mie theory. An example calculation for the coupled microsphere-substrate system was demonstrated in a previous publication [14] using a full-wave simulation approach. It was noted that such conversion process is sensitive to the substrate properties and the gap distance between lens and object. The technique requires gap distance below wavelength scale and ideally a zero distance gap is desired [14]. Besides substrate effect, other factors such as different-NA illumination, incident illumination angle, and microscope image plane have been found also influencing the experimental resolution and magnification. These uncertainties are challenges, but also opportunities for next-generation dielectric superlens development. For example, inspired by enhancing the lens and sample evanescent coupling for a better super-resolution, we recently used high-index TiO$_2$ nanoparticle as building block to form a mouldable micro-sized lens which was deposited on imaging sample, leading to perfect contacting with imaging sample and meanwhile supporting extremely high evanescent-to-propagation conversion efficiency. Such new design of superlens has shown greatly improved imaging contrast and field of view over all previously reported microsphere superlens, and has a record white light super-resolution of 45 nm [25].

Our work reported here laid down a solid foundation for further development of superlens objective lens technology and it is the first kind of such lens in the literature. We are expecting the key problem of contacting scanning will be circumvented in future design, and a contactless superlensing objective lens will be developed. This may be achieved by combining optical superoscillatory mask design with existing superlensing objective design.
5. CONCLUSION

To summarise, we have demonstrated a new type of microscope objective lens, a superlensing objective lens that integrates a conventional objective lens and a coverslip-like microsphere superlens. The new lens has advantages in usability and is able to image the sample with super-resolution in both static and scanning modes. A resolution of 1.00 nm under white light illumination has been demonstrated. The developed superlensing objective lens has the potential to be further developed into a commercial product which could transform an existing microscope into a nanoscope.
