17　Amino sugars can be used as indices to evaluate the role of soil microorganisms in active

18　nitrogen (N) cycling in soil. This paper details the assessment of the suitability of GC-C-IRMS

19　for the analysis of ^{15}N-enriched amino sugars as alditol acetate derivatives prior to application

20　of a novel ^{15}N-stable isotope probing (SIP) approach to amino sugars. The efficient

21　derivatisation and clean-up of alditol acetates derivatives for GC was achieved using

22　commercially available amino sugars, including: glucosamine, mannosamine, galactosamine

23　and muramic acid, as laboratory standards. A VF-23MS stationary phase was found to produce

24　optimal separations of all four compounds. The structure of the alditol acetate derivatives was

25　confirmed using GC-MS. For GC-C-IRMS determinations, implementation of a two-point

26　normalisation confirmed the optimal carrier gas flow rate to be 1.7 ml min^{-1}. Linearity of δ^{15}N

27　value determinations up to δ^{15}N$_t$ of 469　±3.1 ‰ (where δ^{15}N$_t$ is the independently measured

28　δ^{15}N value) was confirmed when 30 nmol N　was injected on-column, with the direction of

29　deviation from δ^{15}N$_t$ at low sample amount dependent on the ^{15}N-abundance of the analyte.

30   Observed between- and within-run memory effects were significant (P < 0.007) when a highly

31   enriched standard (469 ±3.1 ‰) was run therefore analytical run order and variation in [15]N-

32   enrichment of analytes within the same sample must be considered. The investigated

33   parameters have confirmed the isotopic robustness of alditol acetate derivatives of amino

34   sugars for the GC-C-IRMS analysis of ^{15}N-enriched amino sugars in terms of linearity over an

35   enrichment range (natural abundance to 469 ±3.1 ‰) with on column analyte amount over 30

36   nmol N.

37

38   Amino sugars are the building blocks of structural biopolymers in many microorganisms and

39   invertebrates, constituting the second largest structurally defined pool of organic nitrogen (ON)

40   in soil, accounting for between 5-12 %.[1] The microbial source-specificity (with minor

41   contributions from other sources) of these compounds enables investigation of the size and

42   activity of bacterial and fungal pools within soil.[1,2] For example, the bacterial contribution to

43   the glucosamine (GlcN) pool from that of fungal origin can be calculated using the conservative

44   mass ratio of GlcN and muramic acid 5-to-1 in soil bacteria.[3–7] Muramic acid (MurN) is solely

45   of bacterial origin, whilst the two other dominant amino sugars quantified in soils,

46   galactosamine (GalN) and mannosamine (ManN) have both bacterial and fungal sources.[3,8]

47   Quantification of amino sugars in soils by gas chromatography (GC) and liquid

48   chromatography (LC) have been utilised to investigate the impact of environmental controls

49   and agricultural practices on the microbial community composition.[3,9–13] These quantification

50   techniques cannot differentiate between amino sugars within the active microbial pool and

51   those in the necromass.[14,15] Therefore, isotopic labelling techniques can be utilised to

52   investigate the dynamics within the active bacterial and fungal communities and the role of the

53   microbial community in the soil-N cycle. Using a compound-specific ^{15}N-SIP approach

54   provides a selective method of tracing the fate of applied ^{15}N-substrates into the microbial

55   community.[16] Furthermore, it is possible to elucidate differences in relative importance of N

56   transformation pathways in the soil N cycle.[3,15–17]

57   A ^{15}N-SIP approach has applied been to amino sugars, determining ^{15}N-incorporation into soil

58   amino sugars using electron ionisation (EI) gas chromatography-mass spectrometry (GC-

59   MS).[2,4,18] These investigations have revealed the differing temporal response within the

60   microbial community to substrate addition and the differing stability of amino sugar residues.[2,4]

61   The incorporation of ^{15}N into amino sugars was determined following acid hydrolysis of parent

62   amino polysaccharides and aldononitrile derivatisation, based on selected ion monitoring of

63   m/z 98.[18] A major drawback of this technique is that isotopic determinations using GC-MS

64   require high ^{15}N-enrichments and therefore high N application rates which can perturb the

65   system and potentially result in ^{15}N isotopic discrimination.[16] Furthermore, this technique

66   employs a N-containing derivative group, which adds substantial uncertainty to N-isotope

67   determinations (see below).

68   A preferred approach to determining nitrogen isotopic compositions of amino sugars would be

69   to use gas chromatography-combustion-isotope ratio mass spectrometry (GC-C-IRMS). This

70   is a much more sensitive (0.5-2.0 ‰; 0.0002 to 0.0008 atom %) method for the determination

71   of δ^{15}N values of N-containing compounds than GC-MS and can achieve far higher levels of

72   high precision and accuracy. Its use would mean that ^{15}N-SIP experiments could use low-level

73   substrate additions, thereby minimising system perturbations and discrimination.[16,19,20] This

74   technique has already been applied to amino acid δ^{15}N value determinations, providing

75   previously inaccessible levels of detail regarding the rate of N and C transfers within amino

76   acids and soil protein fraction[17,21], amino acid uptake dynamics of plants[22] and evidence for

77   microbial N assimilation pathways and differences in microbial processing of N fertiliser.[16]

78   Hence, used in this way, the ^{15}N-SIP approach can provide hitherto unobtainable insights into

79   N-cycling through the amino sugar pool despite the complex nature of soil organic matter

80   (SOM) and the soil N-cycle.[16,17]

81   Extending this GC-C-IRMS approach to amino sugars and exploiting their source-specificity,

82   would enable elucidation of the role of the bacterial and fungal communities in soil N-cycling

83   with N from environmentally relevant substrates applied at low levels of ^{15}N-enrichment at

84   environmentally relevant concentrations.[16] However, the aldononitrile derivatisation strategy

85   is unsuitable for use with GC-C-IRMS due to the addition of one nitrogen atom.[23] Whilst it is

86   possible to apply a mathematical correction to the determined δ^{15}N values, large uncertainties

87   have been observed for δ^{13}C determinations where corrections are applied due to error

88   propagation.[14,24] GC-C-IRMS therefore requires an alternative derivatisation strategy. The

89   alditol acetate derivatisation method, commonly used for sugars and has been applied to amino

90   sugars, was selected as no nitrogen is added through derivatisation, eliminating these additional

91   uncertainties and is therefore preferred for δ^{15}N determinations using GC-C-IRMS.[25,26]

92   The suitability of the GC-C-IRMS method for δ^{15}N value determinations of ^{15}N-enriched

93   amino sugars must be established prior to application to ^{15}N-tracer studies. The suitability of

94   GC-C-IRMS for the analysis of amino acids has previously been established over a range of

95   ^{15}N-enrichments.[16,17,19,27–30] Instrument parameters, such as optimal carrier gas flow rate, which

96   has a direct influence on residence time of analytes in oxidation and reduction reactors of the

97   GC-C-IRMS interface, have been investigated to ensure accurate determination of δ^{15}N values

98   of amino acids.[29] Furthermore, required sample amount for accurate and precise δ^{15}N value

99   determinations have been tested, and found to range from 2 to 100 nmol N on column.[17,29,30]

100   Importantly, for analysis of ^{15}N-enriched compounds, linearity with ^{15}N-enrichment and

101   memory effects (both between- and within-analytical runs) must be considered.[16,17,30] Such

102   assessments of GC-C-IRMS have led to the development of robust methods for the accurate

103   determination of δ^{15}N values of amino acids over a range of ^{15}N-enrichments, allowing

104 applications using ^{15}N-tracer[16,17,21,22,31] and natural abundance (biological, ecological and

105 archaeological[27,32–35] approaches. The suitability of GC-C-IRMS for the determination of δ^{15}N

106 values of alditol acetate derivatives of amino sugars must be assessed before such a method

107 can be applied in similar studies.

108 Herein, we describe the results of our investigations aimed at implementing a new

109 derivatisation and GC methods compatible with GC-C-IRMS, together with a two-point linear

110 normalisation to correct measured δ^{15}N values against amino sugar standards with known δ^{15}N

111 values. Investigations into the effect of carrier gas flow on precision ensure instrumental

112 parameters are optimised for δ^{15}N determinations of amino sugars. The relationship between

113 isotopic linearity, sample amount and ^{15}N-enrichment have been investigated to confirm the

114 suitability of the method for the analysis of ^{15}N-enriched amino sugars. Finally, we investigated

115 the extent to which a ^{15}N-enriched compound can affect the determined δ^{15}N value of amino

116 sugars with lower ^{15}N-abundance within the same analytical run, and within subsequent

117 analytical runs, i.e. 'memory effects', which have previously been reported in analyses of

118 enriched δ^{15}N and δ^{13}C compounds.[30,36–38] Validation of the GC-C-IRMS method for δ^{15}N

119 value determinations of ^{15}N-enriched amino sugars ensures subsequent studies using a ^{15}N-SIP

120 approach to probe the fate of N-substrates in environmental settings are robust.

121

122 **EXPERIMENTAL**

123 **Reagents and standards**

124 A natural ^{15}N-abundance amino sugar standard (1 mg ml^{-1} glucosamine, muramic acid,

125 galactosamine and mannosamine, Sigma-Aldrich, Dorset, UK) was prepared. ^{15}N-enriched

126 glucosamine standards (δ^{15}N value targets between 35 to 500 ‰) were prepared by the addition

127   of 1 mg ml^{-1} solution 98.0 ±0.3 atom % ^{15}N-GlcN (Sigma Aldrich) to a 1 mg ml^{-1} solution of

128   natural abundance GlcN (isotopic dilution calculations are shown in equation S1 and S2).

129   Derivatisation reagents (sodium borohydride (NaBH$_4$), acetic acid and acetic anhydride) were

130   supplied by Sigma-Aldrich (Steinheim, Germany). All solvents were HPLC grade and supplied

131   by Rathburn Chemicals Ltd. (Walkerburn, UK), double-distilled water (DDW) was produced

132   using a Bibby Aquatron still.

133

134   **Amino sugar derivatisation**

135   The alditol acetate derivatisation method for amino sugars was adapted from that reported by

136   Whiton et al.[25] Briefly, dried amino sugar residues were reduced with sodium borohydride (500

137   μl, 100 mg ml^{-1} in DDW) and heated (60 °C, 2.5 h). Excess sodium borohydride was destroyed

138   by the addition of acetic acid-methanol (2 ml; 1:200 *v/v*) and evaporated to dryness using a

139   stream of N$_2$ at 60 °C. This was repeated four times to ensure the complete destruction of

140   residual sodium borohydride. Acetylation was performed by addition of 500 μl of acetic

141   anhydride and heating (100 °C, 2.5 h). The reaction was quenched by freezing at -20 °C (15

142   min) and acetic anhydride subsequently destroyed by the dropwise addition of 2.5 ml of double-

143   distilled water. The alditol acetate derivatives of amino sugars were extracted with chloroform

144   (3 x 2 ml), combined and dried under a gentle stream of N$_2$ at 40 °C. Residues were re-dissolved

145   in 1.5 ml chloroform and the organic phase washed with double-distilled water (2 x 1.5 ml) to

146   remove residual acetic acid produced during acetic anhydride hydrolysis. The alditol acetate

147   derivatives were dissolved in ethyl acetate for subsequent analysis by GC-FID and GC-C-

148   IRMS.

149

150   **Instrumental analyses**

EA-IRMS

Bulk δ^{15}N values for the amino sugar standards and prepared ^{15}N-enriched GlcN standard were determined using elemental analysis-isotope ratio mass spectrometry (EA-IRMS). A Flash EA 1112 Series NC Analyser (Thermo Electron Corporation, MA, USA) was coupled to a ThermoFinnigan Delta^{Plus} XP (Thermo Electron Corporation) *via* a Conflo III interface. Standards (0.2 mg N; n=9) were weighed into tin capsules for analysis. The δ^{15}N values of N_2 generated by the oxidation and subsequent reduction of the samples in the EA was determined in the IRMS. A two-point normalisation was employed using traceable standards to the international $\delta^{15}N_{air}$ scale using caffeine (-25.5 ±0.3 ‰), benzocaine (-0.3 ‰ ±0.2 ‰)[39] and IAEA-305-B (ammonium sulphate; 375.3 ±2.3 ‰ for ^{15}N-enriched GlcN)[40] as normalisation standards and phenacetin (-8.4 ±0.4 ‰)[39] or IAEA-305-A (ammonium sulphate; 39.8 ±0.5 ‰)[40] as quality control materials. Benzocaine and phenacetin standards were distributed during proficiency tests organised by the Forensic IRMS network.[39] Caffeine was an in-house standard normalised against USGS25 (-30.41 ±0.27 ‰)[41] and benzocaine (-0.3 ‰ ±0.2 ‰).[39] IAEA standards were supplied by the International Atomic Energy Agency, Vienna and USGS standard was supplied by the US Geological Society. Detailed error propagation for the δ^{15}N values for natural abundance and enriched AS measured using EA-IRMS and corrected using a two-point normalisation is shown in supplementary information (Equations S3 and S4) and associated error is shown in Table S1.

GC-FID

An Agilent Technologies 7890B GC-FID (Agilent Technologies, CA, USA) fitted with a VF-23ms column (60 m x 0.32 mm i.d., 0.15 μm film thickness; Agilent Technologies) was used for quantification of amino sugars as their alditol acetate derivatives by comparison to an

175   internal standard (myo-inositol; Sigma Aldrich; $\geq$ 99 %). Elution order was determined by GC

176   analysis of individual standards and the known elution order subsequently used for

177   identification. The carrier gas was helium (He) at a flow rate of 2.0 ml min^{-1} and the

178   temperature programme was 70 °C (1 min hold) to 210 °C (30 °C min^{-1}) to 260 °C (10 °C min^{-}

179   ^{1}; 18 min hold). Data was acquired and analysed using Agilent OpenLab Control Panel (version

180   1.0; Agilent Technologies). Figure 1 shows a typical chromatogram of the amino sugar

181   standard.

182

183   ***GC-MS***

184   GC-MS analyses were performed on a Thermo Scientific ISQ Single Quadrapole GC-MS

185   (Thermo Electron Corporation) operated in electron ionisation mode (70 eV, *m/z* ranges of 50 to

186   650 Da). The carrier gas was He and identical GC column and conditions were employed as for

187   GC analysis.

188

189   ***GC-C-IRMS***

190   The δ^{15}N values of amino sugars as their alditol acetate derivatives were determined using a

191   ThermoFinnigan Trace 2000 gas chromatograph coupled via a ThermoFinngan GC-III

192   interface to a ThermoFinnigan Delta^{Plus} XP isotope ratio mass spectrometer (Thermo Electron

193   Corporation). A GC Pal autosampler (CTC Analytics, Zwingen Switzerland) was used to

194   introduce samples via a programmable temperature vaporisation (PTV) inlet (Thermo Electron

195   Corporation). The GC was fitted with the same column as for GC-FID analyses and the

196   temperature ramp was from 70 °C (1 min hold) to 200 °C (30 °C min^{-1}) to 260 °C (12 °C min^{-}

197   ^{1}; 23 min hold). The oxidation reactor was composed of copper (Cu) and nickel (Ni) wires

198   (OEA Laboratories Ltd, Callington, UK) and maintained at 1030 °C. The reduction reactor was

199 composed of Cu wires and maintained at 650 °C. The carrier gas flow rate was tested over a

200 range of flow rates (1.3 to 2.0 ml min^{-1}) to optimise the carrier gas flow for $\delta^{15}N$ value

201 determinations. The carrier gas was helium for which the optimal carrier gas flow was found

202 to be 1.7 ml min^{-1} in constant flow mode. This was used for all subsequent $\delta^{15}N$ value

203 determinations. Data was acquired and analysed using IsoDat NT 3.0 (Thermo Electron

204 Corporation). Figure 2 shows a typical chromatogram for the amino sugar standard mixture

205 including ion current signal for the *m/z* values recorded. It was not possible to completely

206 baseline separate ManN and GalN however determined $\delta^{15}N_d$ of the two compounds did not

207 significantly vary when analysed as a mixture or single compounds (t-test; P>0.05). This

208 indicated the co-elution had little effect on the determined $\delta^{15}N$.

209 The suitability of GC-C-IRMS for $\delta^{15}N$ value determinations of alditol acetate derivatives of

210 amino sugars in terms of linearity across a ^{15}N-enrichment range was investigated using six

211 ^{15}N-GlcN standards (-3.31±0.24 to 469 ±3.1 ‰; 30 nmol N on column; n=6). Sample

212 requirements for consistent $\delta^{15}N$ value determinations for alditol acetate derivatives of amino

213 sugars were assessed using the same ^{15}N-GlcN standards. The amount of analyte introduced on

214 column was: 8, 15, 30, 50 and 180 nmol N (equivalent to 3.2, 6, 12, 20 and 72 nmol N per

215 analyte in the ion source). All analyses were carried out in triplicate sequence runs in order of

216 increasing sample amount (where applicable) and increasing ^{15}N-enrichment. Finally, possible

217 memory effects within the same run and between runs were investigated (see Table S2 for the

218 sequence order used). For within run memory effects, standard solutions containing ^{15}N-

219 enriched GlcN (either 92.7 ±0.95 or 469 ±3.1 ‰) and MurN and GalN (-0.19 ±0.24 and -3.3

220 ±0.24 ‰, respectively) were prepared, derivatised and analysed in triplicate in order of

221 increasing enrichment.

222

Calculations

Two-point normalisation

A two-point normalisation was applied to correct measured $\delta^{15}N$ values using two bracketing standards for both EA-IRMS and GC-C-IRMS analyses. This uses a linear regression of measured and true $\delta^{15}N$ values of standards to normalise measured $\delta^{15}N$ values of unknown samples and assumes any systematic error within the dynamic range is constant or linear.[42]

For optimisation of carrier gas flow rate, the two-point normalisation was conducted with two standards: standard-1 (Std-1, natural abundance amino sugar mixture) and standard-2 (Std-2; ^{15}N-GlcN 31.9 ±0.4 ‰). Only ^{15}N-enriched GlcN standards were used due to lack of commercial availability of a ^{15}N-erniched standard for other amino sugars. Due to the similar chemical structures of the amino sugars, this was deemed acceptable. The two bracketing standards were analysed (n=6) followed by the QC standard (same as Std-1; n=6) and $\delta^{15}N_d$ value of the QC standard calculated using Equation 1, where $\delta^{15}N_d$ is the measured $\delta^{15}N$ value and $\delta^{15}N_t$ is true value of the standards determined independently using EA-IRMS.[42]

$$\textbf{Equation 1: } \delta^{15}N_t^{QC} = \frac{\delta^{15}N_t^{Std1} - \delta^{15}N_t^{Std2}}{\delta^{15}N_d^{Std1} - \delta^{15}N_d^{Std2}} \times \left(\delta^{15}N_d^{QC} - \delta^{15}N_d^{Std2} \right) + \delta^{15}N_t^{Std2}$$

The calibration was accepted if 75 % of the normalised $\delta^{15}N$ values for the QC standard were within ± 0.75 ‰ and the remainder were within ±1.5 ‰, and 1 σ < ± 0.75 ‰. For the bracketing and QC standards. The standard deviation of the standards was calculated based on the gaussian error propagation outlined in Equation S4. These criteria assessed both the accuracy and precision of determinations and are based on the repeated calibrations (n=5) to assess stability and consistency in the instrumental set-up. The QC standard was analysed every 5 analytical runs to check for drift from the two-point normalisation prepared. When QC values did not fit these criteria, instrument maintenance (inlet maintenance and regeneration of oxidation

246 reactor) was conducted and the two-point normalisation repeated. Two-point normalisation

247 was not carried out when investigating linearity with sample amount and ^{15}N-enrichment and

248 during investigation of memory effects, as it was necessary to confirm these parameters before

249 a two-point normalisation could be applied for high ^{15}N-enrichments.

250

251 **RESULTS AND DISCUSSION**

252 **Derivatisation optimisation and chromatographic separation**

253 The alditol acetate derivatisation method was adapted from the procedure described by Whiton et al.

254 using the sodium acetate catalysed derivatisation.[25] Reduction was achieved at 60 °C, allowing a

255 shorter reduction step and the acetylation reagent was destroyed using double-distilled water,

256 as in Pettolino et al.[26] Due to residual acetic acid remaining from extraction of alditol acetate

257 derivatives using chloroform, an additional washing step was added prior to GC analyses.

258 Chromatographic separation was tested on non-polar (HP-5, Agilent Technologies), mid-

259 polarity (DB-35, Agilent Technologies) and high polarity (ZB-WAX (Phenonmenex Zebron)

260 and VF-23ms, Agilent Technologies) columns. The high polarity cyanopropylphenyl

261 substituted stationary phase provided the best separation for GC-FID of the tested columns for

262 the four amino sugar derivatives, as shown in Figure 1, with co-elution of GlcN, GalN and

263 ManN observed on the other tested columns. This column has been previously used for δ^{15}N

264 value determinations with amino acids and minimal interference from the nitrogen-containing

265 column bleed was observed.[29] Furthermore, during subsequent GC-C-IRMS analyses, an

266 individual background correction for each peak was applied (using 5 s of baseline history) and

267 the applied two-point normalisation will correct for any interference from low level column

268 bleed in the baseline.

269

Mass spectral identification

Following chromatographic separation of the AS derivatives, the structures of the alditol acetate derivatives was confirmed using GC-MS. The mass spectra observed for GlcN, ManN and GalN were identical, with characteristic carbon-chain bond cleavage (e.g. $[M-73]^+$, $[M-289]^+$) and subsequent cleavage of acetylated hydroxyl (e.g. $[M-115]^+$ and $[M-331]^+$) and amine ($[M-349]^+$) groups from these fragments allowing identification. The presence of all fragment ions arising from carbon-chain bond cleavage indicated the alditol acetate derivative was acetylated in all hydroxyl and amine positions.[25,43] MurN was derivatised to muramicitol pentaacetate (MPA) in the lactam form, shown by the presence of $[M-42]^+$, indicating the loss of a ketene.[25,43] The lactam containing fragments $[M-277]^+$ and $[M-217]^+$ dominate the spectra and are characteristic of muramic acid.[44] A second alditol acetate derivative of MurN (to muramicitol tetraacetate (MTA) co-elutes with the dominant isomer which has been previously observed.[25]

Variation in precision with column flow

The carrier gas flow rate controls the residence time of amino sugar derivatives in the combustion and reduction reactors during GC-C-IRMS analyses, therefore this parameter is important to optimise for GC-C-IRMS analyses. At low flow rates (1.3 to 1.5 ml min^{-1}), $\delta^{15}N_d$ values determined using GC-C-IRMS compared to independently measured $\delta^{15}N_t$ value are depicted in Figure 3 for three AS. The deviation from $\delta^{15}N_t$ (i.e. depleted or enriched relative to $\delta^{15}N_t$ value) was inconsistent and was not significant (t-test; P>0.5). Importantly, determined $\delta^{15}N_t$ values at low flow rate have high associated standard deviation (1 σ ca. 2.1 ‰), as depicted in Figure 3. The $\delta^{15}N$ values obtained following two-point normalisation at higher flow rates (1.7 to 2.0 ml min^{-1}) have lower associated error (1σ between 0.5 to 0.8 ‰) and were

294   consistent with offline $\delta^{15}N_t$ values. For subsequent analyses, the carrier gas flow rate was set

295   to 1.7 ml min^{-1}, equating to a residence time in both the oxidation and reduction reactor of 2.2

296   s. The implementation of the two-point normalisation when analysing unknown samples to

297   correct against known $\delta^{15}N$ values for amino sugars helps to improve reproducibility and

298   precision of $\delta^{15}N$ values compared to routinely used single point anchoring techniques.[42]

299   The observed oxidation reactor residence time in this study is comparable to that observed in a

300   previous study for amino acids (more than 2.1 s; flow rate of between 0.8-1.4 ml min^{-1}).[29]

301   Residence time is the critical parameter to consider when optimising the instrumental set-up

302   for $\delta^{15}N$ values determinations, adjusting carrier gas flow rate to provide both accurate $\delta^{15}N$

303   value determinations with high precision ($1\sigma < 0.5$ ‰ Pv/iPr ester derivatives of amino acids

304   and $1\sigma < 0.6$ ‰ for alditol acetate derivatives of amino sugars in the present study).[29]

305

Linearity with enrichment

307   Another important parameter to consider, particularly for analysis of ^{15}N-enriched analytes is

308   linearity across a wide range of $\delta^{15}N$ values. The relationship between known $\delta^{15}N_t$ value and

309   values determined by GC-C-IRMS ($\delta^{15}N_d$) was found to be linear ($R^2 = 0.9997$), as depicted in

310   Figure 4. Linearity across the ^{15}N-enrichment range is important to confirm prior to

311   application of two-point-normalisation to compound-specific $\delta^{15}N$ determination as this

312   criteria is assumed in the normalisaiton.[42] Furthermore, across the enrichment range, the error

313   associated with $\delta^{15}N_d$ was less than 4 % of $\delta^{15}N$ value (and the relative error decreased with

314   increased $\delta^{15}N_t$). The relative error observed across the linear $\delta^{15}N$ scale was comparable with

315   other studies[29] and informed subsequent criteria for evaluating fit of the two-point

316   normalisation. This finding confirms the suitability of the GC-C-IRMS system used for the

317   analysis of ^{15}N-enriched amino sugars up to 469 ±3.1 ‰.

318

Required analyte amount

At $\delta^{15}N_t$ values up to 68.6 ‰, at low analyte amounts (below 30 nmol N), $\delta^{15}N_d$ values appeared enriched compared to offline $\delta^{15}N_t$ values (Figure 5a). At higher analyte amount, (above 30 nmol N on column; 12 nmol N entering the ion source) $\delta^{15}N_d$ were both consistent with measured $\delta^{15}N_t$ values for GlcN standards and were more precise (1 σ < 0.7 ‰). Consistency between replicates could be further increased at higher sample amounts (1 σ < 0.5 ‰), however, this must be balanced with chromatographic performance and oxidation and reduction reactor capacity.

At enrichments above 92.7 ‰, low sample amount (15 nmol N on-column) resulted in depleted $\delta^{15}N_d$ values compared to offline $\delta^{15}N_t$ values (for example 469 ‰ shown in Figure 5b). Deviation from $\delta^{15}N_t$ increased with a greater proportion of ^{15}N in the analyte and consistency between replicates was low (1 σ > 5.0 ‰ for 92. 7 ±0.95 ‰ and 1 σ > 50 ‰ for 469 ±3.1 ‰). This observation was the same as for amino acids across a ^{15}N-enrichment range.[30] This has been hypothesised to be due to the relative sizes of peaks in the m/z 28 and m/z 29 traces and sensitivity of Faraday cups used in the IRMS.[30] The m/z 29 cup is 2 orders of magnitude more sensitive than that measuring the m/z 28 ion abundance. The $\delta^{15}N$ values are subsequently calculated by the data acquisition (Isodat NT) based on the relative areas of the m/z 28 and m/z 29 traces, and the relative contribution of these ions can be overestimated at low sample amount (Figure 6). At low ^{15}N-enrichments, low analyte amount causes overestimation of m/z 29 abundance and deviation towards $\delta^{15}N$ enriched values, as shown in Figure 5a. At high ^{15}N-enrichments and low analyte amount, m/z 28 ion abundance is overestimated due to high error associated with this small peak, yielding depleted $\delta^{15}N_d$ values (Figure 5b). Based on these results, it is recommended between 30 nmol and 50 nmol N are introduced on column for each

342   analyte. This range balances the requirement for sufficient analyte amount to ensure true and

343   precise $\delta^{15}N$ value determinations, whilst considering reactor life span and the need for optimal

344   chromatographic performance.

345   This is the first study investigating such sample requirements for amino sugars, although we

346   can compare our findings to the analyte amounts for amino acids. Importantly, the

347   recommended analyte amount determined in the present study is higher than that for natural

348   abundance $\delta^{15}N$ value determinations of amino acids at high accuracy (2 to 15 nmol N on

349   column for high precision 1 σ < 0.5 ‰)[29], but comparable to the amount recommended for

350   ^{15}N-enriched amino acids (100 nmol N on column).[30] With different instrumental set-ups,

351   analyte amount required for accurate determination of $\delta^{15}N$ values for amino acids varied,

352   therefore it is recommended required sample amount for amino sugars is determined when

353   using a different instrumental configuration.[19,29,30]

354

355   **Memory effects**

356   The between-run memory effect was investigated using multiple run sequences (Table S2).

357   Table 1 shows the observed difference in $\delta^{15}N_d$ following analysis of an enriched standard.

358   There was no significant difference between $\delta^{15}N_d$ for the natural abundance standards run

359   between and after one and three 92.7 ±0.95 ‰ standards (P = 0.085; Figure 7a and 7b). There

360   was, however, a significant difference in the determined $\delta^{15}N_d$ of natural abundance standards

361   before and after the analysis of the standard with a $\delta^{15}N_t$ value of 469 ±3.1 ‰ (both one and

362   three enriched standards analysed; P=0.007 and P < 0.001 respectively; Figure 7c and 7d). The

363   natural abundance GlcN standard was 3.19 ‰ and 16.7 ‰ enriched compared to $\delta^{15}N_t$

364   following analysis of one and three enriched standards with a $\delta^{15}N_t$ of 469 ±3.1 ‰, respectively,

365   and 5 and 7 subsequent analyses of the natural abundance standards were required to achieve

366   no significant difference compared to analyses before the 469 ±3.1 ‰ standard; depicted in

367   Figures 7c and 7d. A significant difference was also observed between $\delta^{15}N_d$ of the 92.7 ±0.95

368   ‰ GlcN standard following the analysis of the standard with a $\delta^{15}N_t$ value of 469 ±3.1 ‰ in

369   triplicate (P < 0.001), with an enrichment on 47.6 ‰ in the standard analyses immediately after

370   the analysis of the ^{15}N enriched standards. Six analytical runs of the GlcN standard with a

371    $\delta^{15}N_t$ value of 92.7 ±0.95 ‰ were required before no significant difference in $\delta^{15}N_d$ values was

372   achieved compared to analyses performed before the analysis of the ^{15}N enriched standards

373   (Figure 7e).

374   Within-run memory effects were also investigated, to determine if the analysis of an ^{15}N-

375   enriched analyte within the same run as a natural abundance analyte influenced $\delta^{15}N_d$. When

376   GlcN with a $\delta^{15}N_t$ value of 92.7 ±0.95 ‰ was analysed in the same analytical run as natural

377   abundance GalN, there was no significant difference (P > 0.3) in $\delta^{15}N_d$ when compared to $\delta^{15}N_d$

378   of GalN in the same run as natural abundance GlcN. However, with a standard containing GlcN

379   with a $\delta^{15}N_t$ value of 469 ±3.1 ‰, there was a significant difference in the $\delta^{15}N_d$ of GalN

380   compared to $\delta^{15}N_d$ of GalN eluting after natural abundance GlcN (P < 0.01). Memory effects,

381   with an enrichment of 5.6 ‰ and 3.1 ‰ for GlcN and GalN (both natural abundance)

382   respectively, were also observed in subsequent analyses and 5 repeated injections of the natural

383   abundance standard was required to confirm no significant difference in the $\delta^{15}N_d$ GlcN and

384   GalN before and after the analysis of the ^{15}N-enriched standard. When the enriched GluN ($\delta^{15}N_t$

385   value of 469 ±3.1 ‰) was vented and the instrument returned to straight mode for the natural

386   abundance GalN, there were no significant memory effect was observed, indicating carry-over

387   effects were due the oxidation reactor. Furthermore, there was no significant difference (P >

388   0.1) in the $\delta^{15}N_d$ of MurN when analysed in the same run as GlcN standards with a $\delta^{15}N_t$ value

389   of 92.7 ±0.95 ‰ and 469 ±3.1 ‰ compared to a standard containing natural abundance GlcN,

390   indicating no memory effects for analytes eluting before an enriched analyte.

391   The observed between-run memory effect indicates analyses should be carried out in order of

392   increasing ^{15}N-enrichment to avoid these. Furthermore, when selecting ^{15}N-enriched standards

393   for use as part of the two-point normalisation, care should be taken to ensure there are no

394   between-run memory effects for subsequent standards used in the two-point normalisation and

395   subsequent sample analysis. To avoid within-run memory effects, which occur after a ^{15}N-

396   enriched analyte, it is recommended to vent column effluent at the time of elution of ^{15}N-

397   enriched analytes to accurately determine the $\delta^{15}N_d$ of the later eluting analytes of interest. This

398   is not necessary if all analytes of interest elute prior to the ^{15}N-enriched analyte.

399

400   **CONCLUSIONS**

401   The work described herein has assessed the suitability of alditol acetate derivatives of amino

402   sugars for GC-C-IRMS, negating the need to add additional N atoms, improving the accuracy

403   of $\delta^{15}N$ determinations. Following optimisation of GC and GC-C-IRMS conditions

404   particularly carrier gas flow, $\delta^{15}N$ values can be determined within ± 0.75 ‰ (1 σ < 0.7 ‰)

405   following correction using two-point normalisation. We have demonstrated $\delta^{15}N$

406   determinations are linear up to 469 ±3.1 ‰ and the required sample amount is between 30 to

407   50 nmol N injected on-column to balance $\delta^{15}N$ determination accuracy alongside

408   chromatographic performance and oxidation reactor lifetime. At low on-column N, between

409   replicate error is high and determined $\delta^{15}N$ values systematically deviated from $\delta^{15}N_t$

410   depending on ^{15}N-abundance. Between- and within-run memory effects necessitate analysis in

411   order of increasing enrichment and venting column flow during the elution of the ^{15}N-enriched

412   component. Following the confirmation of the suitability of the derivatives for the GC-C-IRMS

413   determination of $\delta^{15}N$ values for ^{15}N-enriched amino sugars, this method can be applied to a

414 ^{15}N-SIP approach to investigate the role of the bacterial and fungal communities in N-

415 assimilation in the environment.

Figure 7: Effect of enriched standards on $\delta^{15}N_d$ for values of GlcN standards at natural abundance after (a) 92.7 ‰ (n=1); (b) 92.7 ‰ (n=3); (c) 469 ‰ (n=1); (d) 469 ‰ (n=3) and for the 92.7 ‰ standard (e) after 469 ‰ (n=3). The dashed line is the $\delta^{15}N_t$ values for the natural abundance standard (a-d) and for the 92.7 ‰ standard in (e). The grey box represents $\pm$ 1σ. $\bullet$ denotes $\delta^{15}N_d$ values from triplicate sequence runs. * denotes the average of the three analytical runs is significantly different to the $\delta^{15}N_t$ (paired t-test; significance level set at P < 0.05).

Table 1: Observed change in $\delta^{15}N_d$ values after analysis of ^{15}N-enriched GlcN standard for inter-run memory effects and significance of this difference (determined using a paired t-test comparing analyses before and immediately after the analysis of an enriched standard). * denotes a significant P value. The significance level was set at P < 0.05.

Analytical Sequence	$\Delta^{15}N_d$ / ‰	P-Value
92.7 $\pm$0.95 ‰ (n=1) to NA	+0.17	0.263
92.7 $\pm$0.95 ‰ (n=3) to NA	+0.18	0.085
469 $\pm$3.1 ‰ (n=1) to NA	+5.72	0.007 *

469 ± 3.1 ‰ (n=3) to NA   +16.7   < 0.001 *

469 ± 3.1‰ (n=3) to 92.7 ±0.95   +40.0   < 0.001 *
