16 Abstract

A key controller of a planet's rotational evolution, and hence habitability, is tidal dis-17 sipation, which on Earth is dominated by the ocean tides. Because exoplanet or deep-18 time Earth topographies are unknown, a statistical ensemble is used to constrain pos-19 sible tidal dissipation rates on Earth and similar ecoplanets. A dedicated tidal model is 20 used together with 120 random continental configurations to simulate Earth's semi-diurnal 21 lunar tide. The results show a possible ocean tidal dissipation range spanning 3 orders 22 of magnitude, between 2.3GW-1.9TW (1TW=10¹²W). When model resolution is con-23 sidered, this compares well with theoretical limits derived for the energetics of Earth's 24 present day deep-ocean-only environment. Consequently, continents exert a fundamen-25 tal control on tidal dissipation rates and we suggest that if plate tectonics are present 26 on a planet it will induce a time-varying dissipation analogous to Earth's. This will al-27 ter rotational periods over millions of years and further complicate the role of tides for 28 planetary evolution. 29

³⁰ Plain Language Summary

The daylength of a planet is key for habitability because it regulates the rate with 31 which solar radiation is received and redistributed at the surface. A main controller of 32 a planet's daylength is the ocean tide, because the dissipation of tidal energy works as 33 a brake on the planet's spin, increasing the daylength. Tides are sensitive to the con-34 tinental arrangement on a planet, but there are no details of the surface of any exoplanet 35 and only limited information of what Earth looked like in the distant past. The change 36 in Earth's daylength forces the Moon to recede into a higher orbit, but the present-day 37 recession rate is very high and doesn't fit our age models of the moon, implying the tides 38 must have been much weaker in the distant past. Here, we use a series of tidal predic-39 tions for random continental configurations of Earth to provide a range of tidal dissipa-40 tion rates and thus an estimate of how the tides in the deep past may have evolved as 41 Earth's continents grew more and more complex. This research also provides a range of 42 dissipation rates that can be used for simulations of the rotational and orbital evolution 43 of exoplanets. 44

45 1 Introduction

The ocean tides drive and influence a range of geophysical processes. The tidal en-46 ergy dissipated in shallow waters controls shelf sea stratification (Simpson et al., 1990) 47 and sustains a vertical nutrient flux vital for marine primary productivity in shallow and 48 deep environments (Hickman et al., 2012; Williams et al., 2018; Tuerena et al., 2019). 49 In the deep ocean, tidally driven mixing is integral to the global overturning circulation 50 (Kuhlbrodt et al., 2007; Srokosz et al., 2012; Wunsch & Ferrari, 2004), whereas the tidal 51 range during particular geologic periods may exert an influence on the evolution of com-52 plex life (Balbus, 2014). The tides are also a first-order control on orbital evolution for 53 the Earth-Moon system (Bills & Ray, 1999; Munk, 1968). This is illustrated through the 54 current, anomalously high, (3.8 cm yr^{-1}) recession rate of the Moon which does not match 55 its radiometric age of 4.5 Gyr (Dickey et al., 1994; Barnes, 2017). The erroneous assump-56 tion of a constant modern globally integrated dissipation rate suggests an Earth-Moon 57 system age of about 1.5 Gyr (Darwin, 1899; MacDonald, 1964; Munk, 1968). The miss-58 ing factor may be the time-varying effect of the continental configuration on the tide, 59 a condition shown to have driven long-term dissipation variability on Earth (Kagan, 1997; 60 Green et al., 2017). Consequently, the implications of an ocean tide controlled by a plan-61 ets' continental configuration is an important parameter when modelling the orbital evo-62 lution of an ocean bearing planet. 63

To date, there are over 4000 confirmed exoplanets, of which more than 630 are in multi-planet systems (see http://exoplanet.eu/catalog/ for the latest estimate). The masses

of these planets range from gas giants of the order of $\sim 1000 \ M_{\oplus}$ (Earth masses), to less 66 massive objects that are often characterised as terrestrial planets, thought to be simi-67 lar in composition and scale to the terrestrial planets in our solar system (exoplanets.eu). 68 Concurrently, attempts have been made to estimate the 'habitability' of these planets, a condition based on the probability of a given planet being able to support liquid wa-70 ter at its surface (Kasting et al., 1993) – one of many definitions for habitability. This 71 is a function of host star irradiance, planet-star separation and the chemical composi-72 tion of the planet and its climate system (Seager, 2013). These conditions determine the 73 extent of the Habitable Zone, the theoretical shell around a given star at which liquid 74 water could exist, given the appropriate climatic conditions (Kopparapu et al., 2013). 75

As the number of confirmed planets has grown, planets with potential oceans emerge (e.g., Tsiaras et al., 2019), and the number of planets that appear to be within their habitable zone is expected to increase (Batalha et al., 2013). Estimates put the number of planets in the Milky Way as high as $\sim 10^{10}$ (Dressing & Charbonneau, 2015). Since smaller, potentially terrestrial, planets far outnumber the larger gaseous planets (Cassan et al., 2012; Howard, 2013; Fressin et al., 2013), habitable planets may be common.

Little is known about these planets, which has led to the widespread use of numer-82 ical models of potential climatic conditions to determine a probability of a given body 83 hosting water (Seager, 2013), but there are large uncertainties in this approach. For ex-84 ample, varying host-star irradiances and masses, and planetary atmospheric composi-85 tions, masses, rotation rates, eccentricities, and obliquities will drastically alter the con-86 ditions at the surface (Kasting et al., 1993; Williams & Pollard, 2002, 2003; Yang et al., 87 2014; Way et al., 2016; Way & Georgakarakos, 2017; Way et al., 2018; Colose et al., 2019). 88 Few of these simulations, however, consider the effect of a water ocean tide, despite tidal 89 friction being a key controller on orbital evolution, and hence habitability (Bills & Ray, 90 1999; Lingam & Loeb, 2018; Egbert et al., 2004; Green et al., 2019). 91

If a planet's spin frequency is greater than its moon's orbital frequency, tidal fric-92 tion will increase the semi-major axis length and rotational period of the planet, lead-93 ing to a transfer of angular momentum due to the torques exerted on the body (Darwin, 94 1899). This process leads to an increase of the angular momentum of the tide raiser and 95 a decrease in the planet's rotation rate, so the rotational evolution depends on the amount 96 of tidal energy dissipation. This is in turn a function of the height of the tidal bulges and 97 the rheology of the planet's interior (Renaud & Henning, 2017), including the fraction of water on it. On Earth today, the solid body dissipation for the dominating M_2 lunar 99 tide is 0.08TW (Ray et al., 1996), whereas the associated total ocean tidal dissipation 100 rate is 2.4TW (Egbert & Ray, 2001). Obviously, a liquid ocean can provide a more en-101 ergetic tidal response than a solid body alone because it is easier to excite a tide in the 102 ocean than in the solid Earth. 103

There are links between a planet's potential habitability and its rotation rate, e.g., 104 full spin-orbit synchronization at lower rates and the reduction of meridional atmospheric 105 convection at higher rotation rates due to a stronger Coriolis force (Yang et al., 2014). 106 To properly constrain a planet's climatology, and therefore habitability, a range of vari-107 ables, including the rotation rate, topography and land/ocean mask, must be known (Yang 108 et al., 2014; Way et al., 2016; Way & Del Genio, 2019; Colose et al., 2019). So a planet's 109 past, present and future total tidal dissipation rate must be quantified, to improve es-110 timates of those other dependent properties. 111

Here, we constrain the potential range of tidal dissipation on an Earth-like planet using a dedicated numerical tidal model and a large sample of random continental configurations. This will allow us to produce bounds on the potential dissipation rates that can then be used for rotational evolution simulations, and to provide error bounds on simulations of deep-time tides when Earth's surface looked very different from today's.

117 2 Methods

We use OTIS, the Oregon State University Tidal Inversion Software, a well established numerical tidal model that has been used to simulate deep-time past, present and future tides on Earth (Egbert et al., 2004; Green et al., 2017, 2018; Wilmes et al., 2017), and on ancient Venus (Green et al., 2019). The model has been bench-marked against other global non-assimilating tidal models and demonstrated to reproduce Earth's present day tide with a high degree of accuracy (Stammer et al., 2014). It solves the linearised shallow-water equations,

$$\frac{\partial \mathbf{U}}{\partial t} + f \times \mathbf{U} = -gH\nabla(\eta - \eta_{EQ} - \eta_{SAL}) - F, \qquad (1)$$

$$\frac{\partial \eta}{\partial t} = -\nabla \cdot \mathbf{U} \tag{2}$$

where \mathbf{U} is the depth integrated volume transport (the current velocity u times the depth 125 H), g is the gravitational constant, **f** the Coriolis vector, ζ is the tidal amplitude. η_{SAL} 126 is the elevation due to self-attraction and loading (SAL; here set to 8% of the amplitude 127 following Ray (1997)) and η_{EQ} the equilibrium tidal elevation. The model is forced by 128 the astronomical tide generated by the Lunar and Solar gravitational potential. \mathbf{F} = 129 $\mathbf{F}_B + \mathbf{F}_w$ is the total loss of energy to bed friction (F_B) and tidal conversion $(F_w, \text{de-}$ 130 scribing the generation of an internal tide). The scalar product $\mathbf{F} \cdot \mathbf{u}$ thus gives the tidal 131 dissipation rate, D. Bed friction is given by 132

$$\mathbf{F}_{\mathbf{B}} = C_d \mathbf{u} |\mathbf{u}| \tag{3}$$

The drag coefficient, $C_d=0.003$, represents mean seabed roughness and is based on an 133 appropriate value for present day Earth (see, e.g., Taylor, 1920), and **u** is the combined 134 velocity vector of all the tidal constituents. Note that the model is insensitive to the cho-135 sen value of C_d , and sensitivity simulations (not shown) with it varying by a factor 3 did 136 not significantly change the results. However, this may not be the case for aqua-planets 137 (no continents), where the dissipation may scale directly with C_d due to a lack of topog-138 raphy. Futhermore, for Earth-like ocean with fine sediments we do not expect C_d to vary 139 beyond this parameter range. 140

Tidal conversion is important in simulations with topography, and is given by $F_w = C|\mathbf{U}|$, where C is the conversion coefficient given by (Zaron & Egbert, 2006):

$$C(x,y) = \gamma \frac{(\nabla H)^2 N_b \overline{N}}{8\pi^2 \omega}.$$
(4)

Here, $\gamma = 50$ is a scaling factor, N_b is the buoyancy frequency at the seabed, \overline{N} is the average buoyancy frequency in the vertical, and ω is the frequency of the constituent under investigation. Given the surface properties of exoplanets are unknown, the buoyancy frequency is computed from a statistical fit based on observations from present day Earth, or $N(x, y) = 0.00524 \exp(-z/1300)$, where z is the vertical coordinate, and the constants 0.00524 and 1300 have units of s⁻¹ and m, respectively. Tidal conversion will differ for other fluids (ie: liquid Methane), but we assume a water ocean here.

All simulations were performed for three dominating tidal constituents, but we focus our discussion on those representing the principal semi-diurnal lunar (M_2) and solar (S_2) tides. Their respective constituent periods for Earth today are 12.42, 12 and 23.93 hours. Note that OTIS handles tides only; there is no other forcing included in the model and although inertial oscillations are present we only discuss the ocean tides here.

155

2.1 Continental configurations and sensitivity simulations

The model grids were generated using Planet Generator (https://topps.diku.dk/ torbenm/maps.msp), a fractal map generator capable of simulating complex planet sur-

face features, which is feasible because the shape and distribution of continents are ap-158 proximately fractal-like in nature (Goodchild & Mark, 1987; Mandelbrot, 1982). The gen-159 erator produces grey-scale images, where each pixel value is between 1 (white) and 0 (black). 160 Here, the images were 360×180 pixels in size, and a flat-bottomed 'bath-tub' ocean grid, 161 at a horizontal resolution of $1^{\circ} \times 1^{\circ}$, was built by allocating a depth of 4500 m to all 162 grey-scale pixels with a value below 0.2. The aim here is to evaluate the effect of the po-163 sition and complexity of the continents on the tide, and a further series of sensitivity sim-164 ulations on the boundary values was performed, with the coastline at grey-scale values 165 of 0.1 and 0.4, as well as simulations with bottom topography (see below). 166

In total, 120 different continental configurations were evaluated, including an equi-167 librium tide simulation without continents (See Table in Supplementary Material for a 168 summary of all the simulations). As each configuration is unique, all configurations are 169 independent of one another, so their general geometry and relative positions are hetero-170 geneous. This represents (to some degree) the variation that would be expected between 171 planets, and between geological epochs on the same planet. To show the total effect of 172 continent size, ocean basin size and coastal complexity, we use the non-dimensional value 173 $R = L_{tot}/\sqrt{A_{ocean}}$. L_{tot} is the total coastline length (km) and A_{ocean} (km²) is the to-174 tal ocean area. L_{tot} was found by identifying the coordinates of the coastal boundary 175 between individual continents and the ocean. The distance between neighbouring coor-176 dinates were then calculated using a Great-circle technique: the coastal length for each 177 continent was found, and the total global distance was the sum of these values. This is 178 justified as there is little point considering distances smaller than the smallest horizon-179 tal resolution in the grid, although Earths' real tides are influenced by small, non-random 180 181 topographic features.

We also completed two sets of simulations with ocean bathymetry for 8 maps se-182 lected from the population (see below). The first has a set global average depth (SGAD) 183 whereas the second set had a set maximum depth (SMD). Both were computed by mul-184 tiplying the grey-scale values with a constant. It was equal to 4500 for the SMD, so the 185 deepest point will be 4500m and the shallowest 900 m. The SGAD constant was indi-186 vidually chosen so the mean depth of the ocean was 4500m. This gave a maximum depth 187 between 9500–42000m depending on the configuration. Depths of tens of kilometres, for 188 a planet of Earth's radius, is approaching the limit of the shallow-water approximation 189 employed in OTIS. The simulations are summarised in SM Table 1; note that the ex-190 treme cases are not discussed further. 191

These 8 maps, with bathymetry, were also used to test the sensitivity to stratifi-192 cation through simulations with enhanced ($\gamma = 500$ in Eq. (4)) or reduced stratifica-193 tion (using $\gamma = 5$). The 8 maps, but with bathtub bathymetry, were also subject to tests 194 of the effect of the planet's rotation rate by adjusting Earth's day length to 3 hours and 195 8 days respectively, so that the new M_2 periods are 1.51 and 124.20 hours. Only Earth's 196 rotation period is changed, no adjustment is made to the Lunar period of 27.3 days. Note 197 that a rotation period of 8 days still puts the planet within the fast-rotator regime of its 198 climate dynamics (Way et al., 2018). 199

200

2.2 Present Day Earth sensitivity simulations

Three simulations were run for present day Earth. The control used present day 201 ocean bathymetry, the first of two sensitivity simulations had a bathtub ocean with the 202 depth set to 4500m everywhere (see Fig. SM1a-b), whereas the second had Earths' shelf 203 seas removed by setting any ocean initially shallower than 1000m to 1800m to highlight 204 the importance of shelf dissipation. In the control, at the low resolution of $1^{\circ} \times 1^{\circ}$, OTIS 205 overestimates the M_2 dissipation rate by a factor 2.5 compared to observed dissipation 206 rates [Egbert and Ray (2001); see our Fig. SM1], whereas S_2 is overestimated by a fac-207 tor 3. The bathtub configuration is far less dissipative (Fig. SM1b,c) and underestimates 208

the M_2 and S_2 dissipation rates by factors 25 and 200 respectively. Removing shelf seas 209 gives 0.77TW of M₂ dissipation, compared to the 6.3TW of the control. These results 210 make sense dynamically. In a coarse-resolution simulation not enough energy dissipates 211 in the deep ocean due to underrepresented topography. Because the tidal energy is not 212 lost in the deep ocean, the shelf sea currents are overestimated and, with frictional losses 213 being proportional to the cube of the speed, the dissipation is overestimated. The same 214 happens in the bathtub runs, but there is then no shelf to dissipate the energy on, and 215 instead the global rate drops to deep abyssal values. The stratification sensitivity tests 216 can be found in the SM. 217

218 **3 Results**

219

3.1 Dissipation

As anticipated, the addition of continents of increasing complexity generates a more 220 energetic tide, highlighted for the eight examples in Fig. 1 and summarised in Fig. 2; these 221 are labelled A–H in the following and chosen because they cover the parameter space in 222 Fig. 2. The globally integrated dissipation in Fig. 2a scales with the magnitude of con-223 tinental configuration complexity, quantified here as a ratio, R, between the coastline length 224 and the ocean basin area. As R increases, the M₂ tidal dissipation rate follows and soon 225 reaches values two orders of magnitude larger than the rate in the equilibrium tide (i.e., 226 the 2.3 GW at R = 0). The dissipation range for a certain value of R can span nearly 227 an order of magnitude, but 36% of the configurations occur within the 0.1–1 TW range. 228 The S_2 response is generally weak (not shown), with an amplitude of about 45% of M_2 , 229 although some configurations produce an S_2 dissipation that is larger than M_2 because 230 of S_2 resonances, e.g., configuration E. 231

Both M_2 and S_2 reach dissipation maxima at continental distributions which are 232 qualitatively among the most fragmentary, with several small scale topographic features 233 introducing local flow acceleration. For M_2 , the largest dissipation rate is 1.9 TW (Fig. 234 1E), while S_2 peaks at 0.67 TW – values 19 and 260 times larger than in our bathtub 235 Earth simulation and on par with the observed dissipation rates on Earth today (Egbert 236 & Ray, 2001). As the coastline length continues to grow (i.e., R increases), the conti-237 nent area must also increase. This limits the total ocean area and therefore the poten-238 tial for large integrated tidal dissipation rates as there is a smaller ocean to dissipate en-239 ergy in. In the extreme case, we have a planet with a large number of basins too small 240 to host a tide. Thus, as R increases, we can expect dissipation to reduce, such as on a 241 surface with many disconnected basins, smaller than usual in our ensemble. This form 242 was not explicitly tested, but it would have quiescent tides under the conditions we use, 243 potentially expanding this range to a greater number of orders of magnitude. We leave 244 exploration of this limit to future work. 245

There is not a specific configuration, quantified by R, that is especially dissipative; 246 two configurations can have similar R-values, but be qualitatively dissimilar in the ac-247 tual position of the landmasses (e.g., see configurations D and E in Fig. 1). Given that 248 global dissipation rates are dependent on oceanic area, a configuration that elevates dis-249 sipation closer to the equator should result in a larger global value than one with a con-250 tinent of the same shape at higher latitudes. However, a number of the simulations pos-251 sess a polar ocean, e.g. H, or in some cases a single large hemispheric ocean with a large 252 tide. The dissipation in these instances can have a large deviation from what could be 253 expected, demonstrated in the increasing variability above very small *R*-values. 254

²⁵⁵ On present day Earth, deep ocean tidal dissipation is driven by conversion at bathy-²⁵⁶ metric features (Egbert & Ray, 2001). The SMD configurations generally have an en-²⁵⁷ hanced dissipation (see Figure 2b) influenced by the continental configuration. The two ²⁵⁸ sets – bathtub and SMD – are significantly different ($F_{1,119} = 0.49$, p < 0.05), with the

Figure 1. M_2 Tidal amplitudes for the eight selected configurations, A–H. Note the use of two different colour scales: E and F use the second scale, whereas A–D and G–H use the first (which is repeated under panels G–H).

Figure 2. A) R versus the globally integrated dissipation rate, D. Note the selected 8 configurations, labelled A–H, outlined in red. The point at R=0 is the control water-world, the Earth controls are shown as a circle (bathtub), triangle (with bathymetry), and the star is Earth without shelf seas. The colour scale of continent area has been normalised against Earth's present continental area of 5.1×10^7 km². Additional sensitivity simulations can be found in Table S1. Surfaces with some large number of small disconnected basins were not tested **B**) The same configurations, with a form of random bathymetry, Earth without shelf seas and the control are included for comparison.

bathtub dissipation values being poor predictors of the SMD values. The greatest increases 259 are amongst the configurations that were the least energetic without bathymetry, while 260 the bathtub maximum of 1.83TW can be achieved with smaller and less complex con-261 tinents. Because our results span 3 orders of magnitude, any upper limit on Earth's deep ocean dissipation remains highly uncertain, however as our ensemble maxima are 1.83TW 263 and 1.92TW, such a limit may lie close to these values at this resolution. While the vari-264 ance is large ($s^2 = 7.24 \times 10^{10} \text{ TW}^2$), adding bathymetry narrows the range of dissi-265 pation values compared to the runs without: 92% occur within one standard deviation 266 (0.39 TW) of their mean (0.46 TW) with bathymetry, as opposed to 76% without bathymetry, 267 although this still spans two orders of magnitude. 268

269

3.2 Sensitivity simulations

In the SGAD set, the dissipation rises three orders of magnitude at the lowest Rvalue (see Table 1 SM). A consistent feature in these simulations is the convergence towards a common dissipation value as the stratification is strengthened by a factor of 10: the most energetic configurations are dampened whereas those at the scatter's lower bound are enhanced. In the SMD set, shown in Fig 2b, the trend is similar, however the dissipation shows less variability within the R scale, while the examples lose their dependence on R. The spatial distribution of the SMD runs are shown in Fig. 4 SM.

The planet's rotation rate exerts a fundamental control on the tide (Green et al., 277 2019) by setting resonant periods. Increasing Earth's current rotation rate to 3 hours 278 also means the number of semi-diurnal periods in one present day Earth day rises from 279 2 to 8, thereby potentially increasing the energy dissipation over a certain fixed period 280 of time. This is indeed the case in the simulations herein, with dissipation enhanced in 281 each example, setting an upper bound on the scatter. The large increases for maps G 282 and F reflect the contribution of several smaller, resonant basins. With an 8 day day-283 length, dissipation is reduced across all configurations. Crucially, the influence of con-284 tinental configuration is still apparent, with the rotation adjustment conforming to the 285 upper and lower bounds of the scatter seen in Fig. 2a. 286

Our three frequency sensitivity simulations show, unsurprisingly, that dissipation changes when the frequency is changed due to change in the resonant properties of the basins. However, there is not necessarily a continuous trend in the results, nor can we state if we have hit maximum global resonance in terms of rotation. For very fast or slow spin rates resonances become more localised and will not contribute to globally integrated dissipation rates to the same extent as at more moderate rates – see Green et al. (2019) for a discussion.

294

3.3 An influence on the rotational evolution

The slowing of the planets rotation rate is tied to the magnitude of tidal dissipation. In Table 1 we give an estimate of the variability introduced in the day-length, δ LOD, as a function of just the M₂ frequency after 10⁶ years. Eccentricity (e) and obliquity are 0, and we make the assumption that de/dt = 0. From conservation of energy and momentum, for a small moon orbiting a rapidly rotating planet such as the Earth-Moon system, the globally integrated dissipation, D, is related to the evolution of the Earth-Moon separation, a, as:

$$D = \frac{1}{2}anM_{\rm M}(\omega - n)\frac{da}{dt}$$
(5)

where $M_{\rm M}$ is the Moon's mass $(7.347 \times 10^{22} \text{ kg})$, ω is the Earth's angular rotation rate, *a* is the Earth-Moon separation, $n = \sqrt{G(M_{\rm E} + M_{\rm M})/a^3}$ is the mean motion of the Moon $(G = 6.674 \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{s}^{-2})$ is the gravitational constant and $M_{\rm E} = 5.972 \times 10^{24}$

in which I is the rotating Earth's moment of inertia $(8.04 \times 10^{37} \text{kg m}^{-2})$. An alterna-306 tive method is given by MacDonald (1964). It is reasonable to assume that the values 307 computed here and shown in Table 1 are underestimated by up to an order of magni-308 tude because of the relatively coarse resolution used in our model. An elevated dissipa-309 tion of course leads to an increased δLOD and the linear dependence clearly shows the 310 importance of particular geologic features as the values in Table 1 do not consider shelf 311 seas. Alone, the real deep ocean dissipation (0.9TW) gives a δ LOD of 5.1s from Eq. 6 312 over a million years, the total real integrated dissipation (3.6TW) gives 24s, or for just 313 M_2 , 16s. Our simulation without shelf seas slows by ~5s, compared to 42s for the full 314 bathymetry, illustrating the outsized effect of shallow water energy losses on the planet's 315 rotational evolution. 316

317 4 Discussion

Е

F

G

Η

Continental configuration complexity matters in discussions of a planet's tide be-318 cause, for any given Earth-like planet, increasing the number of basins and/or embay-319 ment type features will increase the probability of resonant amplification. Furthermore, 320 increasing the complexity of coastlines generates further energy loss due to acceleration 321 around peninsula-type features. Numerical simulations have been used to test the effect 322 of Earth's former continental configurations and bathymetry on the tide (Bjerrum et al., 323 2001; Green et al., 2017); however, to our knowledge there are no studies attempting to 324 test a general influence of continental complexity on the ocean tide. This is difficult to 325 do rigorously, given the problems in classifying complex non-Euclidean surfaces such as 326 realistic continents, shapes that were once described as 'monstrosities' (Mandelbrot, 1982). 327

Our results put a constraint on the rotational evolution of planets with oceans and 328 are of use for exoplanet estimates and deep time Earth tidal simulations alike. They also 329 highlight the fundamental effect topography has on ocean tides: even with a few small 330 continents or ocean bathymetry the dissipation can deviate by an order of magnitude 331 from the water world estimate. There is also a strong link between rotation rate and dis-332 sipation (Green et al., 2019), and exoplanet rotation is currently difficult to determine 333 from observation. With an equilibrium tide, Kepler-22b (initial rotation period of 1 Day) 334 would have a rotation rate of about 2 Earth days after a 4.5Gyrs, while Proxima Cen-335 tauri b (initial rotation period of 1 Day) would experience a rotation rate of some 12 days 336

(Barnes, 2017). We have shown that even with simple coastlines and a lack of bathymetry,
 the spin down could vary with an order of magnitude, and be order(s) of magnitude larger
 than in the equilibrium case.

As the continents aggregate and disperse during the 400–500Ma-long, super-continent 340 cycle (Matthews et al., 2016), the tides become anomalously energetic during periods 341 when the basins meet the conditions for resonance. A feature of this tectonically driven 342 super-tidal cycle (Green et al., 2018) is a much less energetic tide during super-continental 343 periods and a brief, more energetic state, for a few 10 Ma in between the subcontinents 344 345 (Gotlib & Kagan, 1985; Green et al., 2017). The trend for more complex configurations to be more energetic in our results is analogous to this process and the tectonic setting 346 thus exerts a first order control on the tidal dissipation. For example, the basin config-347 urations in Figure 2E and G are qualitatively similar, yet E is substantially more dis-348 sipative due to its resonant state, whereas the large meridional continent in G blocks the 349 tide. Equally, the range of the dissipation scatter at any point along the complexity scale 350 (R) is roughly an order of magnitude (see Fig. 2a), which is comparable to the super-351 tidal fluctuation. Higher R-values tend to elevate dissipation, but not indefinitely. As 352 continent size increases, a threshold must be reached where ocean area declines and sup-353 presses dissipation. This is a key geologic control on the rotational evolution (see Ta-354 ble 1). 355

Earth's earliest continental crust is considered to have mostly formed between 3– 356 2.5Ga (Korenaga, 2013, 2018), although this is debated. These early landmasses were 357 probably small (Goodwin, 1996; Scotese, 2004): estimates for the Late-Archean suggest 358 that $\sim 12\%$ of Earth's surface area was continental crust, with only 2–3% as emerged 359 land (Flament et al., 2008). This is compared to 42.5% of the surface being continen-360 tal crust today, of which 27.5% is emerged land area (Schubert & Reymer, 1985; Fla-361 ment et al., 2008; Cawood et al., 2013). In the micro-continental configurations in Fig 1A-362 C, a small semi-diurnal tide would be expected, even with the shorter tidal period and 363 day-length at the time (Spalding & Fischer, 2019), but they still elevate the global dissipation by nearly an order of magnitude above the equilibrium tide (Fig 2a). However, 365 this is still two orders of magnitude smaller than in simulations with larger, more nu-366 merous landmasses that generate more complex basins. It is likely that while Earth had 367 a tidal dissipation rate much greater than the equilibrium tide early on in its history, it 368 may have become more energetic with the formation of larger continents. However this 369 result is not a model for an Archean tide; as shown, shelf-sea area and deep-ocean bathymetry, 370 both unknown for the period, would be key controls. 371

The amount of energy dissipated in our simulations suggests an upper limit near 372 1.9TW for the deep ocean dissipation, given the similarity between the simulations with 373 and without bathymetry. If the overestimation due to our coarse resolution is consid-374 ered, a value of $\sim 0.76 \text{TW}$ may be more realistic, supported by the dissipation value pro-375 duced without shelf seas (Fig 2). These values do of course depend upon the topographic 376 properties: even with a randomised bathymetry the influence of continental configura-377 tion is clear, but is not necessarily a good predictor of the tidal dissipation. Also, the 378 smallest bathymetric features in our grids are of the order of ~ 100 km horizontally, and 379 are of a higher relief than the Earth grid. Grid A for example possesses a canyon many 380 thousands of kilometres long. Given the nonlinear dependence on bathymetric slope in 381 Eq. 4), it is possible that the conversion fraction is overestimated, but this is an avenue 382 for future work. 383

The broader implication for Earth-like exoplanets is that while an ocean may raise global tidal dissipation rates, a basin (or basins) with time-varying dimensions due to tectonics will, in a similar fashion to Earth, cause this value to fluctuate considerably over the planet's history. We suggest that it could span three orders of magnitude solely due to continental configuration. Planets with complex ocean bathymetry are likely to have larger tidal dissipation rates, and hence spin down much quicker, than more bath-

tub like oceans. The apparent convergence generated by adding the SMD bathymetry 390 is an argument for including even a randomised ocean floor in planetary tidal models. 391

The tidal modulation by Earth's tectonics gives these results a robust standard to 392 compare against, but the complexity metric may also have implications for Earth's early 393 history, for periods with limited records of continental position and size. 394

Acknowledgments 395

Torben Morgensen's advice on the use of the map generator is acknowledged. The sim-396

ulations were done on Supercomputing Wales, and their support is greatly appreciated. 397

This work was supported by the NASA Astrobiology Program through collaborations 398

arising from our participation in the Nexus for Exoplanet System Science, and by the 399

NASA Planetary Atmospheres Program. RB acknowledges support from NASA grant 400

NNX15AN35G. MJW is thankful for support from the Goddard Space Flight Center's 401

Sellers Exoplanet Environments Collaboration (SEEC), which is funded by the NASA 402

Planetary Science Division's Internal Scientist Funding Model, and the NASA Habitable 403 Worlds Program. The data can be downloaded from the Open Science Framework (https://osf.io/p7ay9/). 404

Constructive comments from two anonymous reviewers greatly improved the manuscript. 405
