**Highlights**

- Oxidation resistance of UN-U<sub>2</sub>N<sub>3</sub>/UO<sub>2</sub> with initial 10 wt% microspheres is better than UO<sub>2</sub>.
- Oxidation onset temperatures are equivalent when using 30 wt% or 50 wt% microspheres.
- UO<sub>2</sub> acts as a protective barrier for the nitride phases.
- TGA triplicate measurements confirm good repeatability and reliability of the results.
- Oxidation mechanism for UN-U<sub>2</sub>N<sub>3</sub>/UO<sub>2</sub> composites is proposed.

### **Abstract**

Composite fuels such as UN-UO<sub>2</sub> are being considered to address the lower oxidation resistance of the UN fuel from a safety perspective for use in light water reactors, whilst improving the in-reactor behaviour of the more ubiquitous UO<sub>2</sub> fuel. An innovative UN-UO<sub>2</sub> accident tolerant fuel has recently been fabricated and studied: UN microspheres embedded in UO<sub>2</sub> matrix. In the present study, detailed oxidative thermogravimetric investigations (TGA/DSC) of high-density UN-U<sub>2</sub>N<sub>3</sub>/UO<sub>2</sub> composite fuels (91-97 %TD), as well as post oxidised microstructures obtained by SEM, are reported and analysed. Triplicate TGA measurements of each specimen were carried out at 5 K/min up to 973 K in a synthetic air atmosphere to assess their oxidation kinetics. The mass variation due to the oxidation reactions (%), the oxidation onset temperatures (OOTs), and the maximum reaction temperatures (MRTs) are also presented and discussed. The results show that all composites have similar post oxidised microstructures with mostly intergranular cracking and spalling. The oxidation resistance of the pellet with initially 10 wt% of UN microspheres is surprisingly better than the UO<sub>2</sub> reference. Moreover, there is no significant difference in the OOT (~557 K) and MRT (~615 K) when 30 wt% or 50 wt% of embedded UN microspheres are used. Therefore, the findings in this article demonstrate that the UO<sub>2</sub> matrix acts as a barrier to improve the oxidation resistance of the nitride phases at the beginning of life conditions.

## 1. Introduction

After the Fukushima Daiichi disaster in 2011, the nuclear community has strived to engineer a successor to the standard uranium dioxide ( $\text{UO}_2$ )-Zr fuel-cladding system within light water reactors (LWRs). This severe accident scenario demonstrated that the standard fuel system degrades rapidly in such extreme conditions [1]. From that point on, many studies have been carried out focusing on fabricating accident tolerant fuel (ATF) materials that can withstand accident conditions for a longer time. These new ATF materials have to maintain or enhance the fuel performance under normal and transient operating conditions, as well as during a potential design basis accident (DBA) and beyond-design basis accident (BDBA) [2].

Uranium nitride (UN) has been considered a promising ATF candidate to substitute  $\text{UO}_2$  in LWRs mainly because of its higher uranium density, thermal conductivity, and similar melting point in comparison with  $\text{UO}_2$  [3]. These improved properties would allow operating the reactor with a lower fuel centreline temperature, which provides the benefit of a higher margin for melting. Additionally, an improved fission density would enable higher burnup, larger power uprates, and longer fuel resident time [4-6] that are often labelled as advanced technology fuel attributes. However, the UN fuel has low oxidation resistance when in contact with the coolant water in the LWR system [7]. In such a situation, the nitride fuel readily reacts with the coolant and loses its structural integrity, resulting in fuel pellet oxidation, pulverisation, washout and relocation.

Composite fuel designs are considered to overcome the lower oxidation resistance of the UN fuel. The main idea of such composites is to combine the UN with a material that has a better oxidation resistance. This material would form a protective barrier around the UN and, therefore, prevent its oxidation. Several materials such as CrN and AlN [8], ZrN [9],  $\text{U}_3\text{Si}_2$  [10,11], and  $\text{UO}_2$  [12-14] have been studied. Among these options,  $\text{UO}_2$  shows great advantages since it is already used as a fuel in LWR, as well as it has a good oxidation resistance when in contact with the coolant water.

Many studies on UN degradation/oxidation have been performed since the 1960s [7,15-26]. Nevertheless, there are few studies in the literature related to the degradation/oxidation of UN- $\text{UO}_2$  composite fuels [25,27], but none of them is related to UN microspheres embedded in  $\text{UO}_2$  matrix. Both previous studies used mixtures of  $\text{UO}_2$  and UN powders to fabricate the composites. Watkins et al. [25] investigated the degradation

behaviour of UN-UO<sub>2</sub> (5-10 wt%) sintered pellets (> 90 %TD) in high-pressure water. The samples were subjected to hydrothermal oxidation in a static autoclave filled with water at high temperatures (523-623 K) and pressures (up to 16.5 MPa), which are relevant to LWR operating conditions for a short duration. The authors concluded that grain boundary attack and spallation are the primary degradation mechanism in hydrothermal oxidation conditions. Shivprasad et al. [27] reported thermogravimetric analyses of UN-UO<sub>2</sub> (5-30 v%) in steam (62-83 %) during heating to 1273 K, and isotherm data for such composites at 623 K under 82 % steam during 12 h. In both thermogravimetric experiments, the addition of UO<sub>2</sub> delayed the oxidation onset temperature when compared to pure UN. So, the autoclave experiments have permitted the reproduction of an LWR-type environment, but have not provided useful information such as the oxidation onset temperature and the maximum reaction rate, as thermogravimetry has provided. Thus, both autoclave and thermogravimetric investigations are relevant and complementary.

An innovative UN-UO<sub>2</sub> accident tolerant fuel has recently been fabricated and studied by the authors of this work [28]: UN microspheres embedded in UO<sub>2</sub> matrix. Since this composite fuel is a new concept, there is no data regarding its oxidation resistance neither using thermogravimetric examination nor autoclave test. As a first approach, thermogravimetric investigations are essential to understand the material parameters which govern the oxidation reactions of this fuel.

In the present study, detailed thermogravimetric (TG) and differential scanning calorimetry (DSC) investigations of the oxidation reactions in a synthetic air atmosphere up to 973 K are reported and discussed. High-density UN-UO<sub>2</sub> (91-97 %TD) composites, within the limits for LWR application [29,30], were selected from our previous study [28] and are investigated here. This work also describes the influence of the amount (wt%) of each phase present in the sintered pellet, i.e. UO<sub>2</sub>, UN and  $\alpha$ -U<sub>2</sub>N<sub>3</sub>, on the oxidation kinetics. Additionally, pure UO<sub>2.13</sub> powder and UN microspheres, as well as UO<sub>2</sub> and UN sintered samples are evaluated and used as references (UO<sub>2</sub> pellet and UN microspheres). As a result of introducing triplicates in the TGA experiments, uncertainties related to the total weight variation (%), oxidation onset temperatures (OOTs), maximum reaction temperatures (MRTs), as well as the reliability of the TG results were obtained and demonstrated. Therefore, from the findings present in this study, future works are encouraged to perform additional investigations to assess the oxidation resistance of this fuel concept in TGA steam oxidation and/or autoclave test in an LWR-type environment.

## 2. Methods

### 2.1 UN-UO<sub>2</sub> composite fuel fabrication

Uranium nitride (UN) microspheres were fabricated by the internal sol-gel process at Chalmers University of Technology [31,32]. The reported amounts of nitrogen, carbon and oxygen, as well as the associated errors in the triplicate measurements (given as one standard deviation), were  $5.72 \pm 0.07$  wt%,  $833 \pm 550$  ppm and  $1010 \pm 150$  ppm, respectively, which give a chemical formula  $U(N_{1.03}C_{0.02}O_{0.02})$ . N and O analyses were performed by the inert fusion method, using a LECO TC436DR equipment inside a nitrogen-filled glovebox ( $< 500$  ppm O<sub>2</sub>) to minimise oxygen incorporation during sample preparation and analyses. The equipment was calibrated before the analyses by running blank samples for the zero calibration and D-lab standard (provided by Degerfors laboratory) containing 9.71 wt% N and 3 wt% O. The calibration standard was run three times and the furnace constants for N and O, respectively of the instrument, were adjusted if the measurement average deviated from the target value by more than 2 %. C analysis was performed by the combustion method using a LECO CS744 instrument. Prior to carbon measurement, triplicate measurements of blank samples and a calibration standard were performed. The blank samples contained the crucible and combustion accelerator (Lecocell-II, to ensure proper heating of every sample), and the results were used for correcting the measurement baseline to zero. The calibration standard used is a drift standard for calibrating the instrument on top of the multipoint baseline calibration of the instrument. The drift calibration standard used was a carbon-containing steel pin standard from LECO containing  $0.799 \pm 0.011$  wt% C. The as-fabricated UN microspheres were kept under argon for the duration of the investigations ( $< 1$  ppm O<sub>2</sub>).

Uranium dioxide (UO<sub>2</sub>) powder was provided by Westinghouse Electric Sweden AB, which had the following properties: O/U ratio of 2.13, fill density of  $2.19$  g/cm<sup>3</sup>, specific surface area (B.E.T.) of  $5.33$  m<sup>2</sup>/g, mean particle size of  $20.20$  μm, and 900 ppm of H<sub>2</sub>O.

Mixtures of 10, 30 and 50 wt% of as-fabricated UN microspheres (52 %TD) and UO<sub>2.13</sub> powder, as well as pure UO<sub>2.13</sub> and UN microspheres, were sintered by the spark plasma sintering (SPS) method at the National SPS Facility in Stockholm/Sweden. This method is a field-assisted sintering technology, which uses low voltage and high current combined with an applied pressure to consolidate powders [33,34]. The mixtures of UO<sub>2.13</sub>

powder and as-fabricated UN microspheres (~4 g in total) were prepared inside a glovebox (< 0.1 ppm O<sub>2</sub>) connected to the SPS machine. The mixtures were manually homogenised in a small beaker (25 mL) for 1 min with a spatula, poured out in an assembled graphite die (with graphite punches), and transferred to the SPS chamber (more details can be found in our previous article [28]). The SPS equipment used in this study is a modified Dr Sinter machine inside a glovebox, under argon atmosphere (< 0.1 ppm O<sub>2</sub>), to minimise sample oxidation during preparation and sintering. The SPS chamber was depressurised to about 2 Pa to sinter the samples at 1773 K and 80 MPa, using the following thermal profile: heating at 100 K/min until 1573 K and then 50 K/min until 1773 K, held at this plateau for 3 min, and cooled to room temperature using two different cooling rates. First, a slow cooling (SC) profile: 10 K/min (1773-1573 K), 20 K/min (1573-1373 K) and 50 K/min (1373-973 K). Second, a fast cooling (FC) profile: 50 K/min (1773-1173 K). In both cases, from 973 K (SC) and 1173 K (FC) on, the cooling held naturally, i.e. no control over the cooling rate was applied. Additional details about the SPS equipment and sample preparation, as well as the sintering procedures, can be found in our previous article [28].

The samples are identified in this paper as UN(X)-UO<sub>2</sub> (SC/FC), where X is the initial weight fraction (wt%) of UN microspheres in the composite, and SC/FC specifies which cooling rate was applied. Table 1 reports the sample identifications and the SPS parameters used in this study.

**Table 1**

Sample identification and the spark plasma sintering parameters.

Material	UN microsphere (wt%)	Cooling rate (K/min)	Sample identification
UO <sub>2.13</sub> powder	0	10 (1773-1573 K), 20 (1573-1373 K) and 50 (1373-973 K)	UO <sub>2</sub> (SC)
UN microsphere	100	10 (1773-1573 K), 20 (1573-1373 K) and 50 (1373-973 K)	UN (SC)
UN-UO <sub>2</sub>	10	50 (1773-1173 K)	UN(10)-UO <sub>2</sub> (FC)
UN-UO <sub>2</sub>	30	10 (1773-1573 K), 20 (1573-1373 K) and 50 (1373-973 K)	UN(30)-UO <sub>2</sub> (SC)
UN-UO <sub>2</sub>	30	50 (1773-1173 K)	UN(30)-UO <sub>2</sub> (FC)
UN-UO <sub>2</sub>	50	50 (1773-1173 K)	UN(50)-UO <sub>2</sub> (FC)

All samples were sintered at 1773 K and 80 MPa for 3 min. SC = slow cooling. FC = fast cooling.

## 2.2 Oxidation experiments

The oxidation kinetics of the samples were assessed by thermogravimetric analyses (TGA) in a synthetic air flow of 20 mL/min, using a TGA Discovery equipment (TA Instruments) with a weight sensitivity of 0.1 µg. The samples were placed in a platinum pan

without cover and heated up to 973 K at 5 K/min, held at this plateau for 10 min, and then cooled to room temperature. Each sintered pellet (~3.5 g, ~6 mm x 5 mm diameter x height) was cracked in small pieces, and about 45 mg were used in the TG experiments. The weight variation (%) was defined as the percentage due to the weight gain during the oxidation reactions. Also, oxidation onset temperature (OOT) was defined as the temperature at which 5 % of the total weight variation was observed [20], while the maximum reaction temperatures (MRTs) were obtained by analyses of the first derivatives of the weight variation curves (%/min). These considerations are suitable to adopt a consistent basis of comparison between each sample.

Three TG replicate measurements were performed for each sample to assess the standard deviations of all mean values of total weight variation (%), OOTs, MRTs, as well as the repeatability and reliability of the TG results. The standard deviations of the mean values were calculated by dividing the standard deviation of each variable (i.e. total weight variation (%), OOTs, MRTs) by the square root of the number of repeated measurements made [35], which is equal to three in our study. As-fabricated  $\text{UO}_{2.13}$  powder and uncrushed UN microspheres were also oxidised to provide insights about their oxidation behaviours and data for comparison with  $\text{UO}_2$  (SC) and UN (SC) samples.

Additionally, differential scanning calorimetry (DSC) analysis was performed in a Netzsch STA 449 F3 Jupiter equipment under a synthetic air flow of 40 mL/min. Approximately 90 mg of UN(50)- $\text{UO}_2$  (FC) composite fuel was characterised by DSC to evaluate the thermodynamics involved during the oxidation of the three phases present in the sintered material, i.e.  $\text{UO}_2$ , UN and  $\alpha\text{-U}_2\text{N}_3$ . The material was also heated at 5 K/min up to 973 K, kept at this temperature for 10 min, and cooled to room temperature.

### 2.3 Characterisation

UN microspheres and  $\text{UO}_{2.13}$  powder were characterised by scanning electron microscopy (SEM) and X-ray diffraction (XRD) to evaluate their morphologies and crystalline structures, respectively. The SEM used in all analyses was an SEM FEI XL30 with the INCA software. The external surfaces of both compounds were examined using the secondary electrons (SE) detector. Bulk morphologies of sintered UN microspheres and  $\text{UO}_{2.13}$  powder, UN (SC) and  $\text{UO}_2$  (SC) samples, respectively, were examined after standard metallographic preparation (grinding and polishing) of pellets that were hot mounted in a

phenolic resin with carbon filler. Colloidal silica suspension (OP-U, 0.04  $\mu\text{m}$ , Struers) was used to perform a final polishing (2 min) to enhance the contrast between the grains of  $\text{UO}_2$  (SC).

The XRD scans of the raw materials were carried out in a Siemens D5000 diffractometer with  $\text{Cu}_{K\alpha}$  radiation (Ni filter),  $2\theta$  ranging between  $20^\circ$  and  $120^\circ$ , with  $2\theta$  step of  $0.02^\circ$  and acquisition time of 9 s for each step. The UN microspheres were milled inside a glovebox filled with argon ( $< 250$  ppm  $\text{O}_2$ ) using a mortar and pestle, and then encapsulated in an air-tight XRD specimen holder (Bruker model A100B138-B141) to avoid any oxidation during the analysis.

After sintering, the external surfaces of the samples were ground to remove the residual graphite foil from the SPS experiments. XRD and elemental analyses had been performed before in sintered pellets and the results showed that the C contents were consistent with the initial materials [36]. Therefore, grinding the sintered pellet surface is enough to remove the bounded graphite paper from SPS.

A modified Archimedean method, with chloroform as the immersion medium, was used to measure the sintered densities of all samples [36]. Afterwards, the sintered pellets were cut longitudinally and milled to powder using a mortar and pestle in an argon-filled glovebox ( $< 250$  ppm  $\text{O}_2$ ) for XRD analyses, using the same equipment, special holder, and parameters. The theoretical densities (TD) were computed based on the weight fractions of each phase after SPS using the Rietveld method and the software MAUD [37]. Before all XRD measurements, the software MAUD were configured with the information from the Siemens D5000 diffractometer (e.g. wavelengths, goniometer radius). Additionally, an instrumental broadening determination (with yttrium oxide) was performed before calculating the lattice parameters and the weight fractions after sintering [38]. The considered TD reference values [39] for  $\text{UO}_2$ , UN and  $\alpha\text{-U}_2\text{N}_3$  were  $10.96$   $\text{g}/\text{cm}^3$ ,  $14.32$   $\text{g}/\text{cm}^3$  and  $11.24$   $\text{g}/\text{cm}^3$ , respectively. SEM examinations were performed in the polished longitudinal cross sections, coated with carbon, using both secondary and backscattered electron (BSE) detectors.

SEM-BSE images were used to estimate the average grain sizes of the  $\text{UO}_2$  phase in the composites using the software ImageJ [40,41]. The averages were computed based on 5 measurements per grain, considering 20 grains per image and 3 images per sample. Brightness and contrast were adjusted to enhance the grain orientation contrasts. In total,

100 measurements per sample were collected and the average grain sizes, with 95 % confident intervals [35], were obtained from these values.

Post oxidised samples were examined using the same SEM equipment to analyse their surface morphologies. Energy-dispersive X-ray spectroscopy (EDS) was also used to identify the chemical elements present in the oxidised samples.

### 3. Results and discussion

#### 3.1 Phase and morphology of the raw materials and non-oxidised samples

Fig. 1 (a) and Fig. 1 (b) report the morphologies of the  $\text{UO}_{2.13}$  powder and UN microsphere, respectively.  $\text{UO}_{2.13}$  powder's morphology was characteristic of the industrial ammonium uranium carbonate (AUC) wet route [42], with internal porosity that mainly contributes to the surface area of the material. UN microspheres were porous, with some cracks on the surface from the fabrication process, and had a density of about 52 % TD [28].

**Fig. 1.** SEM-SE images of the (a)  $\text{UO}_{2.13}$  powder and (b) UN microsphere.  $\text{UO}_{2.13}$  showed a characteristic ex-AUC powder morphology [42], with internal porosity that mainly contributes to the surface area of the material. The as-fabricated UN microspheres showed superficial and internal porosity with a density of ~52 % TD [28].

The XRD patterns of the  $\text{UO}_{2.13}$  powder and  $\text{UO}_2$  (SC) sample, as well as the UN microspheres and UN (SC) sample, are presented in Fig. 2 (a) and Fig. 2 (b), respectively.

The computed lattice parameters were  $0.5459 \pm 0.0001$  nm and  $0.5475 \pm 0.0001$  nm (ref.  $0.5470 \pm 0.0001$  nm [43]) for the  $\text{UO}_{2.13}$  and  $\text{UO}_2$  (SC) phases, respectively. The  $\text{UO}_{2.13}$  data show broader peaks when compared to  $\text{UO}_2$  (SC). This broadening can be attributed to peak overlap owing to the presence of secondary phases such as  $\text{U}_3\text{O}_7$  and  $\text{U}_3\text{O}_8$  [25]. Additionally, a lattice distortion as a result of excess oxygen in the  $\text{UO}_2$  powder [43,44] can cause broadening. These higher oxide phases are intrinsically formed during the conversion process, where the  $\text{UO}_{2.0}$  powder is pacified to  $\text{UO}_{2+x}$  [42,45]. Shifts in the position of the  $\text{UO}_2$  peaks before and after sintering are observed in Fig. 2 (a). These shifts may be a result of the differences in the lattice parameters, as well as thermally induced residual stress in the  $\text{UO}_2$  (SC) sample [46]. Previous studies [25,47] have also attributed the shifts to the variation in the lattice parameters caused by dissolved/excess of oxygen in the lattice, as well as to thermally induced residual stress.

The calculated lattice parameters for the UN microspheres and UN (SC) sample were  $0.4887 \pm 0.0004$  nm and  $0.4889 \pm 0.0001$  nm (ref.  $0.4889 \pm 0.0001$  nm [48]), respectively. Both samples had cubic phases with equivalent lattice parameters, but showed very low intensity peaks at (about)  $28^\circ$  (111) and  $33^\circ$  (200), which correspond to the  $\text{UO}_2$  phase originated from oxygen impurity.

**Fig. 2.** X-ray diffraction patterns of the (a)  $\text{UO}_{2.13}$  powder and  $\text{UO}_2$  (SC) sample, and (b) UN microspheres and UN (SC) sample.  $\text{UO}_{2.13}$  broadening peaks can be attributed to peak overlap owing to the presence of secondary phases such as  $\text{U}_3\text{O}_7$  and  $\text{U}_3\text{O}_8$  [25], as well as  $\text{U}_4\text{O}_9$  [43,44]. Low intensity peaks (\*) are present in the nitrides at (about)  $28^\circ$  (111) and  $33^\circ$  (200), which correspond to the  $\text{UO}_2$  phase originated from oxygen impurity.

Fig. 3 shows SEM images of the non-oxidised sintered samples.  $\text{UO}_2$  (SC) micrographs in Fig. 3 (a) reports a dense microstructure with small and rounded pores ( $< 2 \mu\text{m}$ ) on the grain corners, characteristic of closed porosity at the end of the sintering process [49]. In contrast, the UN (SC) sample in Fig. 3 (b) had a porous structure with large, irregular and interconnected open pores ( $< 14 \mu\text{m}$ ). As studied by Johnson and Lopes [50], zero per cent of open porosity during SPS of UN fuel can be reached at 1650 K with holding pressures of 90-135 MPa and holding times of 2-15 min. In fact, the UN (SC) sample was still sintering at 1773 K after 3 min, as shown in our previous study [28]. This porosity in UN (SC), as a result of sintering coarse UN microspheres (when compared to UN powder [50]), was then originated from an incomplete pore rounding step during the last stage of sintering [49]. Both micrographs represent the sintered densities reported in Table 3: higher density for the oxide (97.5 %TD), and lower density for the nitride (83.8 %TD) pellets.

**Fig. 3.** Micrographs of non-oxidised (a)  $\text{UO}_2$  (SC) and (b) UN (SC) samples. Higher magnification images better show the pores and grains morphologies.  $\text{UO}_2$  (SC) had a dense microstructure with small and rounded pores ( $< 2 \mu\text{m}$ ) on the grain corners, characteristic of closed porosity [49]. Conversely, UN (SC) had a porous structure with large, irregular and interconnected open pores ( $< 14 \mu\text{m}$ ).

The UN- $\text{UO}_2$  composite fuel microstructures described in Fig. 4 (a-d) show that a third phase,  $\alpha\text{-U}_2\text{N}_3$  (sesquinitride), was formed during fabrication as a result of the interaction between  $\text{UO}_2$  and UN [28]. Similar microstructural features were observed in a

previous study of the reaction of  $\text{UO}_2$  with carbon in the presence of  $\text{N}_2$  at 1973 K [51]. Moreover, based on our previous article [28] and published data [12-14], the interaction between the UN and  $\text{UO}_2$  does not depend on the sintering atmosphere and density/morphology/type of the UN phase. Yet, the interaction between the UN and  $\text{UO}_2$  does not depend on the O/U ratio either. As demonstrated by [14], sintering  $\text{UO}_{2.0}$  powder with dense UN pieces (125-1000  $\mu\text{m}$ , 95.7-97.2 %TD) resulted in a second nitride phase. This behaviour may be due to the equilibrium phase of  $\text{UO}_2$ , which describes that the oxide can be present as a hypo-stoichiometric phase ( $\text{UO}_{2-x}$ ) at the sintering temperature and low oxygen potential [52]. The amount of each phase in the sintered materials affected the oxidation kinetics of the samples (details are described in the upcoming sections).

Our previous study [28] showed that sintering the UN- $\text{UO}_2$  composites at low temperatures ( $< 1173$  K) and pressures ( $\leq 40$  MPa), combined with a fast cooling profile, may minimise the amount of the  $\alpha\text{-U}_2\text{N}_3$  phase. Previous studies on the U-O, U-N, and quaternary system U-C-O-N [53-56] provide important information regarding the  $\text{UO}_2$ ,  $\text{U}_2\text{N}_3$ , UN- $\text{U}_2\text{N}_3$ , and UN- $\text{U}_2\text{N}_3$ - $\text{UO}_2$  systems, as well as propose that the formation of the  $\text{U}_2\text{N}_3$  phase during sintering may be minimised by either lowering the sintering temperature or changing the sintering atmosphere to argon.

**Fig. 4.** SEM-BSE images of composite fuels showing (left) low magnification images, as well as samples (a) UN(10)- $\text{UO}_2$  (SC), (b) UN(30)- $\text{UO}_2$  (SC), (c) UN(30)- $\text{UO}_2$  (FC), and (d) UN(50)- $\text{UO}_2$  (FC). The composite microstructures were obtained from longitudinal cross-sections of the pellets at  $\sim 3$  mm from the edge. The same

microstructural features were observed near the pellet edges. A third phase indicated by the arrows,  $\alpha$ - $U_2N_3$  (sesquinitride), was formed in all UN- $UO_2$  composite fuels. The amount of UN microspheres and the cooling rates affected the amount and/or shape of the sesquinitride phase (more details can be found in [28]).

Table 2 reports the average grain sizes of the  $UO_2$  (SC) and UN (SC) samples, as well as of the  $UO_2$  phase in the composites. The computed average grain size for  $UO_2$  (SC) was  $3.2 \pm 0.2 \mu m$ , slightly different from a previous study ( $5.6 \pm 1.6 \mu m$ ) that used similar SPS parameters (1623 K, 40 MPa, 5 min) [47]. This difference may be due to an extra 2 min in the sintering time, since the authors found that the average grain size increases with the sintering time. UN (SC) sample's value was  $3.1 \pm 0.4 \mu m$ , lower than the result obtained by Johnson and Lopes [50]. The authors sintered UN powder by SPS at 1723 K (90 MPa, 3 min) and obtained an average grain size of  $7.3 \pm 0.2 \mu m$ . Since the expected sinterability of micro-sized powder is higher than coarse microspheres [49], this may be the reason why the authors found a larger average grain size. Regarding the composites, as a general rule, the higher the amount of nitride phases in the sample, the higher the average grain size of the  $UO_2$  matrix. Since N forms a solid solution with the  $UO_2$  matrix, such as  $UO_{2-x}N_x$  [28], the grain growth was enhanced with the increase of the UN initial amount [49]. On the other hand, by only changing the cooling rate, the average grain size did not differ significantly when the uncertainties are considered.

**Table 2**

Average grain sizes of the sintered samples computed using ImageJ [40,41], considering 5 measurements per grain, 20 grains per image, and 3 images per sample.

Sample Identification	Average grain size ( $\mu m$ )
$UO_2$ (SC)	$3.2 \pm 0.2$ ; $5.6 \pm 1.6^*$
UN (SC)	$3.1 \pm 0.4$ ; $7.3 \pm 0.2^\dagger$
UN(10)- $UO_2$ (FC)	$4.8 \pm 0.4^*$
UN(30)- $UO_2$ (SC)	$8.1 \pm 0.7^*$
UN(30)- $UO_2$ (FC)	$7.6 \pm 0.6^*$
UN(50)- $UO_2$ (FC)	$9.5 \pm 0.6^*$

\*Ge et al. (1623 K, 40 MPa, 5 min) [47].  $^\dagger$ Johnson and Lopes (1723 K, 90 MPa, 3 min) [50].  $^*$ Values related to the  $UO_2$  matrix.

Fig. 5 presents the powder XRD diffractograms of the sintered samples. In all composite fuels, a sesquinitride phase ( $\alpha$ - $U_2N_3$ ) was present, together with the  $UO_2$  and UN initial phases. The amount of each phase, as well as the sintered and theoretical densities of all samples, are described in Table 3. The weight fractions of UN microspheres decreased in the composite fuels as a result of the interaction between the UN and  $UO_2$  during fabrication,

as demonstrated in our previous article [28]. The amounts of UN microspheres consumed/reacted during fabrication were then 87 %, 87 %, 63 % and 30 % for samples UN (10)-UO<sub>2</sub>, UN (30)-UO<sub>2</sub> (SC), UN (30)-UO<sub>2</sub> (FC) and UN (50)-UO<sub>2</sub> (FC), respectively. Composite fuels with sintered densities of 91-96 %TD were obtained using SPS in just 3 min of sintering time.

**Fig. 5.** X-ray diffraction patterns of the UO<sub>2</sub> (SC) and UN microspheres samples (references), as well as the UN-UO<sub>2</sub> composite fuels. Peaks related to the phase α-U<sub>2</sub>N<sub>3</sub> (ICSD PDF 00-015-0426) are present in all sintered composites.

From Table 3, the final α-U<sub>2</sub>N<sub>3</sub>/UO<sub>2</sub> wt% ratios for the samples UN(30)-UO<sub>2</sub> (SC), UN(30)-UO<sub>2</sub> (FC) and UN(50)-UO<sub>2</sub> (FC) were approximately 0.20, 0.21, and 0.21, respectively. Conversely, the ratio for the sample with (initially) 10 wt% of UN microspheres was ~0.04, which was the lowest value among the composites mainly due to the highest wt % of UO<sub>2</sub>. Thus, for a higher initial amount of UN microspheres (30 wt%, 50 wt%), the final α-U<sub>2</sub>N<sub>3</sub>/UO<sub>2</sub> wt% ratios showed a similar trend in the final composites (~0.20). Furthermore, the sintered/original molar ratios of nitrogen for the UN(10)-UO<sub>2</sub> (SC), UN(30)-UO<sub>2</sub> (SC), UN(30)-UO<sub>2</sub> (FC) and UN(50)-UO<sub>2</sub> (FC) specimens were 0.66, 0.93, 1.13, and 1.03, respectively. These results indicate that most of the initial N was retained in the sintered composites, as experimentally observed during the sintering of pure UN microspheres and a

UN-UO<sub>2</sub> composite; no significant variation in the vacuum pressure at high temperatures (> 773 K) [28].

**Table 3**

Amount of phases and sample densities after sintering.

Sample identification	Amount of phases after sintering (wt%) <sup>*</sup>			Theoretical density (TD) <sup>†</sup> (g/cm <sup>3</sup> )	Sintered density (g/cm <sup>3</sup> ) <sup>*</sup> (% TD)	
	UO <sub>2</sub>	UN	$\alpha$ -U <sub>2</sub> N <sub>3</sub>			
UO <sub>2</sub> (SC)	100	0	0	10.96 [39]	10.69	97.5
UN (SC)	0	100	0	14.32 [39]	12.00	83.8
UN(10)-UO <sub>2</sub> (FC)	95.0 ± 0.8	1.3 ± 0.2	3.7 ± 0.3	11.02	10.47	95.1
UN(30)-UO <sub>2</sub> (SC)	79.8 ± 0.7	3.9 ± 0.2	16.3 ± 0.6	11.14	10.65	95.6
UN(30)-UO <sub>2</sub> (FC)	73.4 ± 0.5	11.1 ± 0.2	15.5 ± 0.4	11.38	10.78	94.8
UN(50)-UO <sub>2</sub> (FC)	53.8 ± 0.4	34.9 ± 0.3	11.3 ± 0.4	12.16	11.11	91.3

<sup>\*</sup>Calculated from the XRD data using the Rietveld refinement method and the software MAUD [37]. <sup>†</sup>Computed based on the weight fractions and individual theoretical densities of UO<sub>2</sub> (10.96 g/cm<sup>3</sup>), UN (14.32 g/cm<sup>3</sup>), and U<sub>2</sub>N<sub>3</sub> (11.24 g/cm<sup>3</sup>) [39]. <sup>\*</sup>Absolute densities measured by a modified Archimedean method, with chloroform as the immersion medium [36].

### 3.2 Oxidation behaviour of the raw materials and ATF composites

TGA measurements were carried out in triplicate to assess the uncertainties and reliability related to the weight variations (%), OOTs and MRTs. However, for the sake of better visualisation, only one result per sample is presented in the following figures in the text. All measurements are available in Appendix A, which shows good repeatability and reliability of the experiments. Therefore, the results obtained from the microanalyses using TGA can be used as a starting point to understand the macro behaviour of the samples.

Weight variation (%) measurements of the specimens oxidised in a synthetic air atmosphere up to 973 K are shown in Fig. 6, which indicates the differences between the nitride, composites, and UO<sub>2</sub> behaviours. The mass decreases observed at high temperatures (> 800 K), in both the nitrides and composites with 30 wt% and 50 wt% of UN microspheres, are also observed in previous studies [24,48]. According to these previous studies, the mass decreases can be interpreted as the release of nitrogen (as N<sub>2</sub> gas) from an intermediate oxynitride product that is formed during the oxidation of the nitride phases. We have not detected nitrogen in the SEM-EDS examinations; only oxygen and uranium as chemical elements were present in all the oxidised samples.

**Fig. 6.** Weight variations of all samples as a result of the oxidation reactions. Mass decreases at high temperatures ( $> 800$  K) in the nitrides samples, as well as in the composites with 30 wt% and 50 wt% of UN microspheres, can be interpreted as nitrogen release from an intermediate oxynitride that is formed during the oxidation of the nitride phases [20,48].

Theoretical weight variations were obtained using the reactions described in Table 4, considering that the ultimate product in all experiments was  $U_3O_8$  and that the nitrogen exits the samples as  $N_2$  gas [7,17,20,57]. These theoretical values were compared to the ones obtained from the TG results, with their deviations described in Table 5 as a percentage change (% change). The errors associated to the real values were obtained by considering the maximum and minimum values from the TG results. The percentage change was defined as the difference between the theoretical and real values divided by the theoretical one. All samples showed small weight variation uncertainties ( $\leq \pm 0.17\%$ ) and percentage changes ( $\leq 4.5\%$ ), indicating that the equations in Table 4 can describe the oxidation of the specimens, as well as showing good repeatability of the experiments. The weight variation of  $UO_2$  (SC) (3.94 %) was only 0.3 % different from the stoichiometric  $UO_2$  pellet. When the errors in both real and theoretical values are considered, the weight gain (real) of the samples UN (SC), UN (30)- $UO_2$ , and UN (50)- $UO_2$  can be considered equivalent to the respective theoretical values. Sample UN (10)- $UO_2$  was the only one that presented a real value slightly inferior to the theoretical one (the highest percentage change, 4.5 %).

The weight variation of the  $UO_2$  (SC) sample (3.94 %) in Table 4, when compared to the theoretical value (3.95 %), indicates that the  $UO_{2.13}$  powder reduced to stoichiometric  $UO_2$  during sintering. Previous studies using spark plasma sintering [47] and conventional

sintering [58-60] in vacuum atmospheres demonstrated that the  $\text{UO}_{2+x}$  powder was reduced to  $\text{UO}_{2.0}$  during the sintering process. Ge et al. [47] justified the powder reduction as a result of the interaction between the graphite foil (from the SPS die) and  $\text{UO}_{2+x}$  to form UC on the pellet surface (XRD result). After grinding the pellet to remove the graphite foil, only the  $\text{UO}_2$  phase was present in the XRD diffractogram. Kutty et al. [58] studied the sintering behaviour (dilatometry) of  $\text{UO}_{2.15}$  up to 1673 K in vacuum, demonstrating that the shrinkage curves for vacuum exactly coincided with that for Ar and Ar-8 %  $\text{H}_2$ . Therefore, the reduction of  $\text{UO}_{2+x}$  to  $\text{UO}_{2.0}$  can happen independent of the sintering process (SPS or conventional sintering) and sintering atmosphere (Ar, vacuum,  $\text{H}_2$ ).

**Table 4**

Theoretical oxidation reactions occurred in the oxidation thermogravimetric experiments, considering that the  $\text{U}_3\text{O}_8$  phase was the ultimate product in all experiments [7,17,20,57].

Oxidation reaction	Equation	Remark
$3 \text{UO}_2 + \text{O}_2 \rightarrow \text{U}_3\text{O}_8$	(1)	$\text{UO}_2$ (SC) pellet oxidation reaction.
$6 \text{UN} + 8 \text{O}_2 \rightarrow 2 \text{U}_3\text{O}_8 + 3 \text{N}_2$	(2)	UN (SC) pellet oxidation reaction.
$3 \text{U}_2\text{N}_3 + 4 \text{O}_2 \rightarrow 2 \text{U}_3\text{O}_8 + 4.5 \text{N}_2$	(3)	Oxidation of $\alpha\text{-U}_2\text{N}_3$ present in the sintered samples.
$x \text{UO}_2 + y \text{UN} + z \text{U}_2\text{N}_3 + \text{O}_2 \rightarrow \text{U}_3\text{O}_8 + \text{N}_2$	(4)*	Overall oxidation reaction of the sintered samples.

\*x, y and z are related to the amounts of  $\text{UO}_2$ , UN and  $\alpha\text{-U}_2\text{N}_3$ , respectively, present in the sintered pellets (Table 3).

The oxidation onset and maximum reaction temperatures, extracted from the weight variation curves (Fig. 7, Fig. 8, Fig. 9), are summarised in Table 5. The uncertainties related to both OOTs and MRTs are also described, showing a minimum variation of  $\pm 1$  K and a maximum of  $\pm 9$  K.

**Table 5**

Average values of the weight variations, oxidation onset temperatures, and maximum reaction temperatures of the sintered samples.

Sample Identification	Weight variation (%)			Oxidation onset temperature (OOT) (K) <sup>†</sup>	Maximum reaction temperature (MRT) (K) <sup>♦</sup>
	Theoretical	Real	% Change <sup>*</sup>		
$\text{UO}_2$ (SC)	3.95	$3.94 \pm 0.00$	0.3	$570 \pm 5$	$704 \pm 2$
UN (SC)	11.37	$11.25 \pm 0.15$	1.1	$533 \pm 2$	$604 \pm 9$
UN(10)- $\text{UO}_2$ (FC)	$4.21 \pm 0.08$	$4.02 \pm 0.01$	4.5	$593 \pm 6$	$713 \pm 3$
UN(30)- $\text{UO}_2$ (SC)	$4.96 \pm 0.10$	$5.02 \pm 0.02$	1.2	$556 \pm 1$	$641 \pm 4$
UN(30)- $\text{UO}_2$ (FC)	$5.46 \pm 0.08$	$5.57 \pm 0.05$	2.1	$560 \pm 5$	$618 \pm 3$
UN(50)- $\text{UO}_2$ (FC)	$7.04 \pm 0.08$	$7.10 \pm 0.17$	0.9	$557 \pm 1$	$610 \pm 2$

\*% Change =  $100 \times |\text{Real} - \text{Theoretical}| / \text{Theoretical}$ . <sup>†</sup>Oxidation onset temperature (OOT) is defined as the temperature at which 5 % of the total weight variation was observed. <sup>♦</sup>Maximum reaction temperatures (MRTs) were obtained by analyses of the first derivatives of the weight variation curves.

Fig. 7 portrays the weight variation curves for the raw materials,  $\text{UO}_2$  (SC) and UN (SC) samples. The first derivatives of each curve, here named as reaction rates, are also plotted in the figure. The oxidation of the  $\text{UO}_{2.13}$  powder (Fig. 7 (a)) showed two oxidation steps: the first one is associated to a parabolic oxidation curve, while the second one is related to a sigmoid weight variation curve. The first step corresponded to the formation of  $\text{U}_4\text{O}_9/\text{U}_3\text{O}_7$  on  $\text{UO}_2$  powders, following a diffusion-controlled mechanism [61]. The results showed an OOT and MRT of  $440 \pm 3$  K and  $458 \pm 2$  K, respectively, and a weight gain of 0.86 % up to 523 K, which is in agreement with the formation of the  $\text{U}_3\text{O}_7/\text{U}_4\text{O}_9$  phases [57]. The second step, associated with a sigmoid curve, is interpreted as the oxidation of the  $\text{U}_3\text{O}_7/\text{U}_4\text{O}_9$  phases into  $\text{U}_3\text{O}_8$  by a nucleation and growth mechanism [62]. OOT and MRT of this step were  $623 \pm 3$  K and  $631 \pm 3$  K, respectively, with a total weight variation of  $2.47 \pm 1$  %, which is in agreement with a previous TG analysis [63].

Fig. 7 (b) shows the complete oxidation of  $\text{UO}_2$  (SC) into  $\text{U}_3\text{O}_8$ , with a total weight variation of  $3.94 \pm 0.00$  %; quite similar to the nominal value of 3.95 % (Table 5). In the  $\text{UO}_2$  (SC) case, the oxidation followed a sigmoid curve in one major step: from  $\text{UO}_2$  to  $\text{U}_3\text{O}_8$ . The oxidation started with incubation time, at which a fine layer of  $\text{U}_3\text{O}_7$  was formed on the external surface, followed by a parabolic kinetic ( $\sim 623 - 680$  K), and then a linear kinetic ( $\sim 680 - 750$  K) until the complete oxidation into  $\text{U}_3\text{O}_8$  [57,61]. The OOT ( $570 \pm 5$  K) and MRT ( $704 \pm 2$  K) for  $\text{UO}_2$  (SC) were higher than the  $\text{UO}_{2.13}$  powder, since the oxygen chemisorption and the diffusion-controlled formation of  $\text{U}_3\text{O}_8$  are both proportional to the surface area [57,64,65]. Thus, the higher the surface area, or the smaller the particle size, the faster the oxidation process.

UN microspheres and UN (SC) weight variation curves are presented in Fig. 7 (c) and Fig. 7 (d), respectively. The oxidation behaviours of both samples are similar, with sigmoid curves and total weight variation close to the nominal value of 11.37 %. The OOT for the UN microspheres ( $549 \pm 1$  K) was slightly higher than the UN (SC) ( $533 \pm 2$  K). As previously demonstrated [20], the oxidation resistance of the UN samples can be improved by eliminating open porosity. In our case, however, open porosity was not the only parameter that affected the oxidations. Yet, since the densities of the UN samples were different, the surface areas of both samples were also different and impacted the oxidation behaviour. Thus, a combination of higher open porosity and surface area of the UN microspheres (52 %TD), compared to UN (SC) (83.8 %TD), resulted in an OOT increment of about 16 K. Regarding the MRTs, the microspheres showed a lower temperature and higher

rate, indicating that the formation of  $U_3O_8$  was faster after the formation of an oxide layer during the incubation time. These results were expected since the UN microspheres were porous, which provides more surface area to be attacked during oxidation. Our ongoing work is focused on optimising the UN- $UO_2$  composite by using denser (80-95 wt%, based on previous studies [66-68]) and coated UN microspheres to avoid the interaction between UN and  $UO_2$ , as well as to delay the oxidation onset temperature of the UN microspheres.

**Fig. 7.** Weight variation curves (solid lines) and reaction rates (dashed lines) of (a)  $UO_{2.13}$  powder, (b)  $UO_2$  (SC), (c) UN microspheres (52.0 %TD), and (d) UN (SC) (83.8 %TD). The average values and the uncertainties of the oxidation onset temperatures (OOTs) and the maximum reaction temperatures (MRTs) are indicated in the graphs.  $UO_{2.13}$  powder showed a two steps oxidation curve, while the other samples had a single sigmoid shape: oxidation of  $UO_2$  (or UN) into  $U_3O_8$ .

The amount of UN microspheres affected the oxidation kinetics of the composite fuels, as reported in Fig. 8. For the same cooling rate, e.g. fast cooling (FC), the higher the UN content in the sintered composites, the higher the total weight variation. Additionally, there was a sesquinitride phase in the sintered composites,  $\alpha-U_2N_3$ , that formed during fabrication as a result of the interaction between UN and  $UO_2$  (Fig. 4, Fig. 5, [28]). The oxidation of this sesquinitride also contributes to increasing the total weight variations. As reported in Table 3, the total amount of UN +  $\alpha-U_2N_3$  in UN(10)- $UO_2$  (FC), UN(30)- $UO_2$  (FC) and UN(50)- $UO_2$  (FC) were 5.0 wt%, 26.6 wt% and 46.2 wt%, respectively. Regarding the grain sizes of the  $UO_2$  phase of the composites (Table 2), the higher the initial weight fraction of UN microspheres, the larger the average oxide grain sizes in the final

pellets. The initial oxidation rates, up to (about) 50 % yield, were faster when the matrix grain sizes increased. Quémard et al. [69] found that the oxidation rate up to ~ 50 % yield increased when the grain sizes diminished. This different behaviour might be because they were analysing pure  $\text{UO}_2$  sample, as well as owing to additional complexity of the UN- $\text{UO}_2$  system: sesquinitride precipitates along and inside the  $\text{UO}_2$  grain and UN embedded microspheres. Therefore, the initial oxidation rates in Fig. 8 depended not only on the average oxide grain sizes, but also on the nitride amounts in the sintered samples, which seemed to impact much more the rates than the grain sizes themselves.

Fig. 8 also reports the influence of the initial amount of microspheres on the OOTs and MRTs. The OOT of UN(10)- $\text{UO}_2$  (SC) ( $593 \pm 6\text{K}$ ) was surprisingly 23 K higher than the reference  $\text{UO}_2$  (SC). Additionally, the composite showed a slightly higher MRT and lower oxidation rate at the maximum point, indicating that the oxidation reaction was more moderate in the composite than in the  $\text{UO}_2$  (SC) reference. A previous study [23] proposed that the formation of U-N-O compounds on the surface of nitrated uranium can resist the diffusion of oxygen ions into the inner layer. Also, Lu et al. [19] showed that the corrosion resistance of the  $\text{U}_2\text{N}_3$  phase is better than the U or UN phase structure films. Thus, the complexity related to the U-O-N system seems to retard the oxygen diffusion through the sample in some cases. Increasing the initial amount of UN microspheres from 10 wt% to 30 wt% and 50 wt% have not affected the OOTs. Also, these composites had similar OOTs when compared with the  $\text{UO}_2$  (SC) reference. These results seemed to demonstrate that the  $\text{UO}_2$  matrix provided a barrier against oxidation of the nitride phases. However, the reaction occurred approximately three times faster in UN(50)- $\text{UO}_2$  (FC) ( $0.84 \pm 0.14 \text{ %/min}$ ) than in UN(30)- $\text{UO}_2$  (FC) ( $0.29 \pm 0.01 \text{ %/min}$ ) at the maximum rates, since the amount of nitrides was the highest in UN(50)- $\text{UO}_2$  (FC).

**Fig. 8.** Influence of the initial amount of UN microspheres (wt%) on the (a) weight variations and (b) reaction rates. The oxidation behaviour of UN(10)-UO<sub>2</sub> (SC) was similar to the UO<sub>2</sub> (SC) reference. The composite showed a higher OOT and MRT, as well as slower reaction rate at the maximum point. No changes in OOT was observed when the initial amount of UN microspheres changed from 30 wt% to 50 wt%. These results seemed to demonstrate that the UO<sub>2</sub> matrix provided a barrier against oxidation of the nitride phases.

The influence of the cooling rates on the oxidation kinetics is reported in Fig. 9. The faster the cooling, the higher the nitride amounts in the sintered composite and, consequently, the greater the total weight variation. Samples UN(30)-UO<sub>2</sub> (SC) and UN(30)-UO<sub>2</sub> (FC) had a total amount of nitrides of 20.2 wt% and 26.6 wt%, respectively (Table 3). Concerning the OOTs reported in Fig. 9 (a), the cooling rate affected neither the chemisorption of oxygen onto the composites, nor the diffusion-controlled formation of U<sub>3</sub>O<sub>8</sub> during the early oxidation stage (< 523 K) [57,64,65]. Thus, the OOTs for the composites were quite similar to the UO<sub>2</sub> (SC) reference, when the uncertainties are considered, demonstrating that the UO<sub>2</sub> matrix retard the oxidation of the nitride phases. Nevertheless, the MRTs were affected by the cooling rate (Fig. 9 (b)). In the case of UN(30)-UO<sub>2</sub> (FC), the oxidation reaction reached a maximum of  $0.29 \pm 0.01$  %/min at  $618 \pm 3$  K, while the slowly cooled sample showed a slightly lower reaction rate ( $0.26 \pm 0.01$  %/min) at a higher temperature ( $641 \pm 4$  K). Therefore, the cooling rate affected directly the amount of UN +  $\alpha$ -U<sub>2</sub>N<sub>3</sub> in the composites and, consequently, the oxidation kinetics: the faster the cooling, the higher the amount of nitrides and the reaction rate, and the lower the MRT.

**Fig. 9.** Influence of the cooling rate on the (a) weight variations and (b) reaction rates. OOTs for the composites were similar to the UO<sub>2</sub> (SC) reference, indicating that the UO<sub>2</sub> matrix acted as a barrier to retard the oxidation of the nitride phases. The faster the cooling, the lower the MRT. This behaviour is directly affected by the highest amount of UN +  $\alpha$ -U<sub>2</sub>N<sub>3</sub> in the sample UN(30)-UO<sub>2</sub> (FC): 26.7 wt% against 20.2 wt% (slow cooling).

From the DSC data plotted in Fig. 10, two linear kinetic regions associated with exothermic peaks are observed: first, between 573 K and 650 K; and second, between 660 K and 685 K. At these regions, a proposed mechanism for the composite oxidation is that the reaction occurred via UO<sub>2</sub> grain boundary attack at fresh UO<sub>2</sub> surfaces that formed during cracking and nucleation/growth of U<sub>3</sub>O<sub>8</sub> after an incubation time [57,65,69,70]. Simultaneously to the grain boundary attack, the  $\alpha$ -U<sub>2</sub>N<sub>3</sub> phase oxidised since it was present along and inside the UO<sub>2</sub> grains (Fig. 4). With the extent of reaction, the embedded UN microspheres were also reached by oxygen and resulted in a strong exothermic DSC peak at 673 K, which is characteristic of a highly exothermic nitride phase oxidation [15]. Therefore, the UO<sub>2</sub> addition was beneficial to retard and smooth the oxidation of the nitride phases.

**Fig. 10.** Differential scanning calorimetry analysis of UN(50)-UO<sub>2</sub> composite fuel heated at 5 K/min up to 973 K at 40 mL air/min. Normalised UO<sub>2</sub> (SC) and UN microspheres weight variations (from TGA) are plotted as illustrative references. The DSC data showed two linear kinetic regions associated with exothermic peaks: 573-650 K and 660-685 K. Additionally, the UO<sub>2</sub> addition reduced the severity of the oxidation reaction and retarded the oxidation of the nitride phases.

### 3.3 Post oxidation morphology

Fig. 11 shows the micrographs of the as-fabricated and oxidised UO<sub>2.13</sub> powder, UO<sub>2</sub> (SC), UN microspheres, and UN (SC) samples. UO<sub>2.13</sub> powder's overall morphology has not changed after its oxidation, which is known to have a complex kinetic above 473 K owing to a simultaneous formation of U<sub>3</sub>O<sub>7</sub> and U<sub>3</sub>O<sub>8</sub> [71]. Since the powder had an initial surface area of 5.33 m<sup>2</sup>/g, with most of it coming from internal porosity (Fig. 1 (a)), a net increase of ~36 % in volume due to its oxidation to U<sub>3</sub>O<sub>8</sub> [70] might have been compensated by porosity and, then, avoided macro-cracking. Conversely, the oxidised UO<sub>2</sub> (SC) sample showed a general surface roughening and spalling after oxidation, as illustrated by SEM-SE images of a fragment in Fig. 11. As previously presented in [57,61] and discussed in section 3.2, the U<sub>3</sub>O<sub>8</sub> formation on the UO<sub>2</sub> (SC) pellet occurred after the formation of a U<sub>3</sub>O<sub>7</sub> layer at the beginning of the reaction. This layer increased until reaching a critical thickness and then spalled from the UO<sub>2</sub> as powder, generating cracks at the pellet surface. These cracks can be associated with a stress state created by the U<sub>3</sub>O<sub>7</sub> on UO<sub>2</sub>, since the U<sub>3</sub>O<sub>7</sub> phase has a smaller lattice parameter than the UO<sub>2</sub> phase [69]. Afterwards, the oxidation reaction continued via grain boundary attack, with simultaneous cracking and nucleation/growth of U<sub>3</sub>O<sub>8</sub> at the freshly created surfaces via linear kinetics until consuming all UO<sub>2</sub> [57,65,69,70]. Fig. 11 shows that macro-cracks were mostly formed at the UO<sub>2</sub> grain boundaries, with some

micro-cracks inside the grains as well. Additionally, there are small fragments in the image that could have been generated during transportation, since the cohesive forces in the oxidised  $\text{UO}_2$  samples are weak and may crack into powder when weak stress is applied [69].

UN microspheres and UN (SC) samples showed similar oxidation kinetics (Fig. 7 (c,d)) and post oxidised microstructures (Fig. 11). As a general behaviour, the growth mechanism of the  $\text{U}_3\text{O}_8$  phase might have followed a succession of steps, such as adsorption of oxygen on the external surface, including inside the microspheres' open pores, and external interface reaction followed by diffusion through the  $\text{U}_3\text{O}_8$  towards the freshly UN internal phase. The cracks observed in the UN samples seemed to occur at the beginning of the sigmoid curves, after reaching a critical oxide layer (similar to the  $\text{UO}_2$  pellet) [57,61], and then inducing a rapid increase of the oxidation rates (Fig. 7 (c,d)) due to new reactive and fresh surfaces of UN. Furthermore, oxidation along grain boundaries introduced large stresses that the brittle nitride samples were unable to withstand. Similar intergranular cracking and spalling behaviours have been observed during hydrothermal oxidation of UN at 523-623 K and pressures up to 16.5 MPa [25], as well as during steam oxidation at 573 K and 9 MPa [21].

**Fig. 11.** Micrographs of as-fabricated and oxidised  $\text{UO}_{2.13}$  powder,  $\text{UO}_2$  (SC), UN microspheres, and UN (SC) samples.  $\text{UO}_{2.13}$  powder's morphology did not change significantly after oxidation. Similar post oxidised microstructures with mostly intergranular cracking and spalling were observed in the  $\text{UO}_2$  (SC) and nitrides samples.

Fig. 12 reports the micrographs of the as-fabricated and oxidised UN- $\text{UO}_2$  composite fuels. In general, the oxidised morphologies showed a corroded surface with intergranular cracking and spalling, and some intragranular cracks as well. As discussed in section 3.2, the formation of a critical oxide layer generated cracks at the surfaces, which enhanced the reaction rates by nucleation and growth of  $\text{U}_3\text{O}_8$  on a freshly surface. Ex-situ SEM examinations did not allow a complete visualisation on how the oxidation reactions evolved. A previous article reports in-situ oxidation of  $\text{UO}_2$  fuel pellet at 603 K and  $P_{\text{O}_2} = 265$  Pa up to 5.5 h [69]. The authors demonstrated that two types of cracks occurred during oxidation: first, macro-cracks occurred at the grain boundaries after 30 min of isothermal oxidation, followed by micro-cracking at the cracked surfaces that enhanced spallation. They also showed that the

sample was still oxidising when the pellet was completely cracked with a constant weight variation, i.e. no more reactive surfaces was created. At this final stage, nucleation and growth of  $U_3O_8$  proceeded until the total consumption of the  $UO_2$  phase.

**Fig. 12.** Micrographs of as-fabricated and oxidised UN(10)- $UO_2$  (FC), UN(30)- $UO_2$  (SC), UN(30)- $UO_2$  (FC), and UN(50)- $UO_2$  (FC) composite fuels. All the oxidised morphologies had a corroded surface with mostly intergranular cracking and spalling, with some intragranular cracking as well.

#### 4. Conclusions

This article is presenting, for the first time, thermogravimetric experiments in triplicates concerning the oxidation resistance of high-density (91-97 %TD) UN- $U_2N_3/UO_2$  composite fuels in a synthetic air atmosphere below 973 K. The results show that the

oxidation resistance of the composite with initially 10 wt% of UN microspheres is surprisingly better than the  $\text{UO}_2$  reference. The OOT of UN(10)- $\text{UO}_2$  (SC) ( $593 \pm 6$  K) is about 23 K higher than the reference  $\text{UO}_2$  (SC). Additionally, this composite shows a slightly higher MRT and lower reaction rate at the maximum rate, indicating that the oxidation reaction is smoother in the composite than in the  $\text{UO}_2$  (SC). Additionally, there is no significant difference in the OOTs ( $\sim 560$  K) and MRTs ( $\sim 613$  K) when using 30 wt% or 50 wt% of embedded UN microspheres. These behaviours are a direct result of the improved oxidation resistance provided by the  $\text{UO}_2$  phase, which acts as a protective barrier for the nitride phases. Nevertheless, the oxidation reaction occurs approximately three times faster in UN(50)- $\text{UO}_2$  (FC) ( $0.84 \pm 0.14$  %/min) than in UN(30)- $\text{UO}_2$  (FC) ( $0.29 \pm 0.01$  %/min) at the maximum rates, since the total amount of nitrides (UN +  $\alpha$ - $\text{U}_2\text{N}_3$ ) is the highest in UN(50)- $\text{UO}_2$  (FC) (46.2 wt%). Regarding the cooling rates, the faster the cooling process during fabrication, the higher the total nitride contents in the sintered composites. This behaviour results in an expected higher total weight variation in UN(30)- $\text{UO}_2$  (FC) ( $5.57 \pm 5$  %) than in UN(30)- $\text{UO}_2$  (SC) ( $5.02 \pm 2$  %).

DSC analysis of UN(50)- $\text{UO}_2$  (FC) demonstrates more clearly that the oxidation of the composite fuels seems to follow two linear kinetics regions at 573-650 K and 660-685 K. At these regions, a proposed mechanism is that the oxidation occurs via  $\text{UO}_2$  grain boundary attack at freshly exposed  $\text{UO}_2$  surfaces that are formed during cracking and nucleation/growth of the  $\text{U}_3\text{O}_8$  phase. During the grain boundary attacks, it is suggested that the  $\alpha$ - $\text{U}_2\text{N}_3$  phase oxidise since it is present along and inside the  $\text{UO}_2$  grains. With the extent of reaction, the UN phase is also reached by oxygen and results in a strong exothermic DSC peak at 673 K. The oxidised composites have similar morphologies, showing a corroded surface with mostly intergranular cracking and spalling as a result of the oxidation reactions. Furthermore, the nitrides and  $\text{UO}_2$  (SC) microstructures have a general roughening and spalling with intragranular and some intergranular cracks. Conversely, the overall morphology of the  $\text{UO}_{2.13}$  powder does not change after its oxidation.

The findings in this study demonstrate that the  $\text{UO}_2$  matrix acts as a barrier to improve the oxidation resistance of the nitride phases as they would exist at the beginning of life conditions. Therefore, the use of the  $\text{UO}_2$  fuel to protect the UN microspheres is promising and requires future developments/tests to be used as an accident tolerant fuel in LWR.

## 5. Appendix

All TGA experiments were performed in triplicate. The results for the raw materials, as well as for the  $\text{UO}_2$  (SC) and UN (SC) samples, are plotted in Fig. A1. The coloured/bolded graphs are the data used in the article, and the grey curves indicate the replicates.

**Fig. A1.** Triplicate measurements of (a)  $\text{UO}_{2.13}$  powder, (b)  $\text{UO}_2$  (SC), (c) UN microspheres, and (d) UN (SC). The coloured/bolded curves are the ones used in the article. The results show good repeatability and reliability of the TGA experiments, with the largest discrepancy occurring in UN (SC) between 550-650 K.

**Fig. A2.** Triplicate measurements of (a) UN(10)-UO<sub>2</sub> (FC), (b) UN(30)-UO<sub>2</sub> (SC), (c) UN(30)-UO<sub>2</sub> (FC), and (d) UN(50)-UO<sub>2</sub> (FC). The coloured/bolded curves are the ones used in the article. The results show good repeatability and reliability of the TGA experiments.
