25 Abstract

Plastic accumulating in the environment, especially microplastics (defined as 26 particles <5 mm), can lead to a range of problems and potential loss of ecosystem 27 services. Polyhydroxyalkanoates (PHAs) are biodegradable plastics used in the 28 manufacture of mulch films, and packaging as an alternative to minimize plastic 29 30 residue accumulation and reduce soil pollution. Little is known, however, about the effect of microbioplastics on soil-plant interactions, especially soil microbial 31 community structure and functioning in agroecosystems. For the first time, we 32 33 combined zymography (to localize enzyme activity hotspots) with substrate-induced growth respiration to investigate the effect of PHA addition on soil microbial 34 community structure, growth, and exoenzyme kinetics in the microplastisphere (i.e. 35 interface between soil and microplastic particles) compared to the rhizosphere and 36 bulk soil. We PHA used the common biopolymer, 37 poly 38 (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) to show that PHBV was readily used by the microbial community as a source of carbon (C) resulting in an increased 39 40 specific microbial growth rate and a more active microbial biomass in the 41 microplastisphere in comparison to the bulk soil. Higher β -glucosidase and leucine aminopeptidase activities (0.6-5.0 times higher V_{max}) and lower enzyme affinities 42 (1.5-2.0 times higher K_m) were also detected in the microplastisphere relative to the 43 44 rhizosphere. Furthermore, the PHBV addition changed the soil bacterial community at different taxonomical levels and increased the alpha diversity, as well as the relative 45 abundance of Acidobacteria and Verrucomicrobia phyla, compared to the untreated 46 soils. Overall, PHBV addition created soil hotspots where C and nutrient turnover is 47 greatly enhanced, mainly driven by the accelerated microbial biomass and activity. In 48 conclusion, microbioplastics have the potential to alter soil ecological functioning and 49

- 50 biogeochemical cycling (e.g., SOM decomposition).

- 53 matter

54 1. Introduction

Synthetic polymers are widely used in our daily lives (Wright and Kelly, 2017), 55 and more than 280 million tons of plastics are produced annually (Duis and Coors, 56 2016; Sintim and Flury, 2017). Despite the remarkable benefit of plastics to society, 57 there are increasing concerns associated with the vast amount of plastic entering our 58 59 environment and its subsequent resistance to degradation (Rochman, 2018). These concerns are supported by estimates that > 30% of the world's plastic waste is 60 disposed of inappropriately, with most ultimately entering the soil ecosystem 61 62 (Jambeck et al., 2015; Weithmann et al., 2018). In soils, larger plastic debris often becomes fragmented by biota and physical disturbance into smaller pieces known as 63 microplastics (mean diameter < 5 mm), which have received increased attention 64 globally, due to their potential to cause environmental damage (Rillig, 2012; Wright 65 and Kelly, 2017; de Souza Machado et al., 2019). A promising approach to overcome 66 the accumulation of microplastics in soils is to replace traditional petroleum-based 67 plastics with biodegradable bioplastics like polyhydroxyalkanoates (PHAs; Gross and 68 69 Kalra, 2002; Volova et al., 2017). PHAs account for 5.6% of the global production 70 capacity for biodegradable polymers, and represent the second fastest growing group in the market sector since 2014 (Haider et al., 2019). Even though PHAs are used in 71 an attempt to decrease microplastic residues in terrestrial ecosystems, and praised as 72 73 promising alternatives for a diverse range of applications (e.g., mulch films for agriculture), the potential environmental consequences of PHAs have not yet been 74 thoroughly studied. 75

Unlike petroleum-based microplastics, which biodegrade extremely slowly, PHAs can be broken down by a range of organisms and are not thought to produce any harmful by-products (Volova et al., 2017; Haider et al., 2019; Sander et al., 2019).

Their biological source also means that they are viewed as C neutral (Garrison et al., 79 2016), although this assumes that they don't induce positive priming of soil organic 80 81 matter (SOM). Furthermore, they are supposed to not enhance N_2O and CH_4 release which might offset these benefits. Given that PHAs are C-rich but nutrient-poor (i.e. 82 no N and P; Gross and Kalra, 2002; Volova et al., 2017), they may alter microbial 83 community composition and functioning during degradation. Since the decomposition 84 85 of C-rich residues is associated with N and P immobilization, subsequent plant growth may also be affected due to the increased competition between plants and soil 86 87 microorganisms for nutrients (Qi et al., 2018; Qi et al., 2020b; Song et al., 2020; Zang et al., 2020). In response to the additional C supplied from PHAs breakdown, the 88 turnover of native SOM may be stimulated due to the altered metabolic status of the 89 90 microbial community (Kuzyakov, 2010; Zang et al., 2017), and thus influence soil C and nutrient cycling. PHAs are also naturally present in soil being produced as storage 91 compounds by the bacterial community (Mason-Jones et. al. 2019). Given that 92 bacteria are more sensitive to environmental changes (e.g. increased labile C) 93 compared to fungi (Barnard et al., 2012), soil bacteria may have a stronger response 94 due to the increased C availability through PHAs breakdown. This will lead to 95 significant long-term impacts on a range of soil ecosystem services (e.g., C storage, 96 nutrient cycling, and pollutant attenuation; Zang et al., 2018). Although recent studies 97 revealed that microplastics may have divergent influences on soil microbial 98 communities and enzyme activities, e.g., activation (Liu et al., 2017; de Souza 99 Machado et al., 2019), suppression (Fei et al., 2020), or remaining unchanged (Zang 100 et al., 2020), the effect of microbioplastics on soil microorganisms remain poorly 101 understood. Therefore, it is vital to investigate how biodegradable microplastics affect 102 microbial functions and below-ground C processes (Zang et al., 2019, 2020; Qi et al., 103

104 2020a).

Similar to plant-soil interactions in the rhizosphere, the main processes affected 105 by microplastic input may occur at the soil-plastic interface (here defined as the 106 microplastisphere). We hypothesize that these interactions are stimulated by the input 107 of labile C present in microbioplastics (i.e. increased microbial activity, attract or 108 favor specific bacterial taxa, and interfere with belowground plant-microorganisms 109 110 interactions) leading to the formation of microbial hotspots in soil, similar to those seen in the rhizosphere (Kuzyakov and Blagodatskaya, 2015; Zang et al., 2016; Zhou 111 112 et al., 2020b). Following PHAs addition, we predict that changes in soil physico-chemical properties will only occur close to the microplastic particles, with 113 changes in the bulk soil (non-hotspot) likely to be minor (Zettler et al., 2013; Huang 114 et al., 2019). The specific niches of the microorganisms in the microplastisphere are 115 of ecological relevance, given that most agricultural soils are contaminated by 116 microplastics (Steinmetz et al., 2016; Qi et al., 2020a). However, it still remains 117 unclear how PHAs affect soil microbial communities in hotspots and, thus, alters soil 118 C and nutrient cycling. 119

Here, for the first time, we coupled zymography, a method to accurately locate 120 microbial hotspots (Hoang et al., 2020; Zhang et al., 2020), the kinetics of exoenzyme 121 activities involved in C, N, and P cycling, microbial growth, and bacterial community 122 structure to evaluate microbial functions, as well as soil process in hotspots 123 (rhizosphere microplastisphere) bulk 124 and and soil. Polv (3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) represents a commercially 125 available copolymer used for mulch film production. Compared to PHB, it has higher 126 flexibility, thermal stability, and processibility due to the monomeric composition, 127 which makes it promising as a typical example of PHAs (Table. S1; Jiang et al., 2009; 128

Bugnicourt et al., 2014). Therefore, we aimed to 1) identify microbial hotspots in situ 129 in soil treated with PHBV; 2) investigate the effect of biodegradable microplastics on 130 131 microbial growth and enzyme kinetics; 3) evaluate changes in bacterial community structure and function in the microplastisphere and rhizosphere. We hypothesized that: 132 1) the labile C in PHBV will greatly alter soil bacterial community structure and 133 functioning compared to the rhizosphere and bulk soil, and 2) the microplastisphere 134 135 contains microorganisms with a high growth rate and enzyme activity in comparison to rhizosphere and bulk soil. 136

137

138 **2. Materials and methods**

139 2.1 Site description and sampling

140 Soil samples were taken from the Ap horizon (0-20 cm) of an experimental field at the Reinshof Research Station of the Georg-August University of Göttingen, 141 Germany (28°33'26"N, 113°20'8"E). This experimental site was established more 142 than 40 years ago and the farming history is clear. No plastic mulch was applied, and 143 no plastic pollution was recorded for the site. The soil was air-dried, sieved (<2 mm), 144 and mixed to achieve a high degree of homogeneity and to reduce the variability 145 among replicates. Fine roots and visible plant residues were carefully removed prior 146 to use. The soil contained 1.3% total C, 0.14% total N, and had a pH of 6.8 (Zhou et 147 al., 2020b). Ten percent (w/w) of the soil dry weight was added as poly 148 (3-hydroxybutyrate-*co*-3-hydroxyvalerate) 149

([COCH₂CH(CH₃)O]m[COCH₂CH(C₂H₅)O]n (PHBV). PHBV was obtained in a
pelletized form from the Tianan Biologic Materials Company Ltd., Beilun, Ningbo,
China. PHBV represents one of the most widespread and best characterized members
of the PHA family (Bugnicourt et al., 2014). It is a 100% biobased thermoplastic

linear aliphatic (co-)polyester obtained from the copolymerization of 154 3-hydroxybutanoic acid and 3-hydroxypentanoic acid which are produced through the 155 bacterial fermentation of sugars and lipids (Zinn et al., 2001). Most of the PHBV is 156 composed of hydroxybutyrate, however, a small fraction of hydroxyvalerate is present 157 in its polymeric backbone (Rivera-Briso and Serrano-Aroca, 2018). This type and 158 amount of highly crystalline plastic were chosen to simulate the localized disposal of 159 160 bioplastics in agricultural soils (e.g., ploughing in of mulch film residues at the end of the field season) and was based on field investigations and a review of the literature 161 162 (Fuller and Gautam, 2016; Qi et al., 2020a). We added very high amounts of microplastic to reflect soil hotspots with higher contamination levels (1-20%). 163

164

165 2.2 Experimental design

A mesocosm experiment with a completely randomized design and four 166 replicates was set up in a climate-controlled room. For the PHBV addition treatment, 167 400 g soil and PHBV were mixed homogeneously and then placed in a rhizobox (10 imes168 169 10×4 cm; Qiangsheng Co., Ltd. Heibei, China). The control treatment contained soil (400 g) without PHBV, but with a comparable soil disturbance. The soil bulk density 170 was maintained at 1.2 g cm⁻³ for all rhizoboxes. Prior to use, the soil was 171 pre-incubated under field-moist (25% v/v) conditions in a greenhouse for one week to 172 173 allow the soil to equilibrate. Before planting, wheat (Triticum aestivum L.) seeds were sterilized in 10% H₂O₂ for 10 min, then rinsed with deionized water and germinated 174 on wet filter paper. Five days after germination, seedlings were transplanted in 175 rhizoboxes (one seedling per rhizobox), and then moved to the climate-controlled 176 chamber (day/night regime of 14 h/24 °C and 10 h/14 °C, respectively). The relative 177 humidity in the chamber was maintained at 40% and the plants were received 800 178

 μ mol m⁻² s⁻¹ photosynthetic active radiation (PAR) at canopy height (Zhou et al., 2020b). Plants were watered every three days and the soil moisture was maintained at a gravimetric moisture content of 25% throughout the experiment by weighing the rhizoboxes.

183

184 *2.3 Hotspot identification*

At 24 days after transplanting, zymography was used to visualize three 185 hydrolytic enzymes Razavi et al. 2016). Given that β -glucosidase, acid phosphatase, 186 and leucine-aminopeptidase play a corresponding major role in cellulose, organic 187 phosphate, and protein degradation (Lopez-Hernandez et al., 1993; Lammirato et al., 188 2010), there reflects key enzymes related to soil C, P and N cycle, respectively 189 (German et al., 2011). Polyamide membrane (Tao yuan, China) were saturated with 190 4-methylumbelliferyl (MUF) and 7-amido-4-methylcoumarin (AMC) based substrate 191 to visualize the specific enzymes. Each substrate was separately dissolved in 10 mM 192 MES and TRIZMA buffer for MUF and AMC, respectively. The saturated membranes 193 were placed on soil surfaces containing root systems and covered with aluminum foil 194 to avoid water evaporation and moisture changes during the incubation period (Hoang 195 et al., 2020). After incubation for 1 h, the membrane were carefully lifted off the soil 196 surface and any attached soil particles were gently removed with tweezers and a soft 197 brush (Razavi et al., 2016). Enzyme detection sequences followed as: β-glucosidase, 198 acid phosphatase, leucine-aminopeptidase activity, with 1 h interval after each 199 zymography. The grey scale values transferred to the enzyme activities was calibrated 200 using membranes $(2 \times 2 \text{ cm})$ saturated with a range of concentrations of 201

202 corresponding products, i.e. MUF and AMC (0. 0.01, 0.2, 0.5, 1, 2, 5 mM).

The zymograms were transferred into a 16-bit gray scale by ImageJ with a 203 correction for environmental variations and camera noise (Razavi et al., 2016). The 204 calibration line obtained for each enzyme was used to convert gray values of each 205 zymography pixel into enzyme activities (Hoang et al., 2020). Enzyme activities 206 exceeding 25% of mean corresponding activity of the whole soil were defined as 207 hotspots (Zhang et al., 2020). Specifically, soil with a high color intensity (dark-red) 208 represents microbial hotspots, whilst dark-blue colors indicate bulk soil on the 209 210 zymograms (Fig. 1; Hoang et al., 2020). Given the hotspots in the control and PHBV-treated soil were detected at the distance within 1.5-2 mm from the roots and 211 microplastics, the hotspots in the control and PHBV-treated soil were identical as the 212 213 rhizosphere and microplastisphere zones, respectively (Fig. 1). After collecting soil from hotspots and bulk soil, a total of 16 samples [2 treatments (without and with 214 PHBV)×2 microsites from each treatment (hotspots and bulk soil)×4 replicates] were 215 216 obtained.

217

218 *2.4 Plant and soil sampling*

At 25 days after transplanting, the shoots were cut off at the base of the stem and the roots were collected separately. For precise localized sampling, soil particles were carefully collected using needles (tip 1.5 mm) directly from the hotspots (rhizosphere and microplastisphere) identified by zymography (Fig. 1). Bulk soil was collected in a similar way. Once collected, soil samples (hotspots and bulk soil) were separated into two sub-samples. One sub-sample was stored at -80 °C to analyze the bacterial community structure, while another sub-sample was used to measure enzyme kinetics and the kinetics of substrate-induced growth respiration directly. After removal of the hotspot samples and bulk soil, the remaining soil in the rhizobox was mixed and then stored at 4 $^{\circ}$ C to measure microbial biomass N, dissolved organic C and N. Shoots and roots were oven-dried (60 $^{\circ}$ C, 5 days) and then weighed.

230 Soil microbial biomass N (MBN) was extracted with K₂SO₄ (32 mL, 0.05 M), 231 and calculated with a corresponding K_{EN} factor of 0.45 according to Wen et al. (2020). Briefly, the fresh soil was homogenized and 8 g sub-sample of the soil was extracted 232 233 with K₂SO₄ (32 mL, 0.05 M). Another 8 g sub-sample of the soil was fumigated with chloroform for 24 h and then extracted in the same way. Total C in extracts was 234 measured using a 2100 TOC/TIC analyzer (Analytik Jena GmbH, Jena, Germany). 235 The non-fumigated extractions were used as a measure for dissolved organic C (DOC) 236 and N (DON). 237

238

239 2.5 Enzyme kinetics

The activity of the exoenzymes β -1,4-glucosidase (BG) (EC 2.2.1.21), leucine 240 aminopeptidase (LAP) (EC 3.4.11.1), and acid phosphatase (ACP) (EC 3.1.3.2) were 241 determined 4-methylumbelliferyl 242 by the (MUF)-based and 7-amido-4-methylcoumarin (AMC)-based artificial substrates (Marx et al., 2001; Wen 243 et al., 2019). Briefly, 0.5 g soil was mixed with 50 ml sterile water and then shaking 244 for 30 min. After 2 min low-energy sonication (40 J s⁻¹) by ultrasonic disaggregation, 245 50 µl of the soil suspension, 50 µl of corresponding buffer (MES or TRIZMA) and 246 100 µl of the corresponding substrates at concentrations of 2, 5, 10, 20, 50, 100 and 247 200 µmol 1⁻¹ were pipetted into 96-well black microplates (Brand[®] plates pureGrade, 248

249 Sigma-Aldrich, Germany). The Victor 1420-050 Multi label Counter (Perkin Elmer,

USA) was used to measure the fluorescence at an excitation wavelength of 355 nm
and an emission wavelength of 460 nm. Enzyme activities were taken at 4 times (0,
30 min, 1 h and 2 h), and was expressed as nmol g⁻¹ soil h⁻¹.

To calculate key parameters describing the enzyme kinetics, we fitted a Michaelis-Menten equation to the experimental data (Marx et al., 2001):

255
$$V = \frac{V_{\max} \times [S]}{K_m + [S]}$$
(1)

where V is the enzymatically mediated rate of reaction, V_{max} is the maximal rate 256 of reaction, $K_{\rm m}$ (Michaelis constant) is the substrate concentration at $\frac{1}{2}V_{\rm max}$ and S is 257 substrate concentration. The substrate turnover time (T_t) was calculated according to 258 the following equation: T_t (hours) = $(K_m + S) / V_{max}$, where S is the substrate 259 260 concentration (200 μ mol l⁻¹). The catalytic efficiency of enzymes (K_a) was calculated by the ratio of V_{max} and K_{m} (Hoang et al., 2020). The microbial metabolic limitation 261 was quantified by calculating the vector lengths and angles of enzymatic activity for 262 all data based on untransformed proportional activities (e.g. (BG):(BG+LAP), 263 (BG):(BG+ACP)) (Moorhead et al., 2016). 264

265

266 2.6 Kinetics of substrate-induced growth respiration

The substrate-induced growth respiration (SIGR) approach was used to distinguish total and active biomass fractions, as well as microbial specific growth rate and lag-time before growth (Zhang et al., 2020; Zhou et al., 2020a). It should be noted that although C substrate addition is required for the SIGR approach, all kinetic parameters analyzed by SIGR represent the intrinsic features of dominating microbial populations before substrate addition (Blagodatsky et al., 2000).

One gram of fresh soil was amended with a mixture containing 10 mg g^{-1} glucose, 273 1.9 mg g^{-1} (NH₄)₂SO₄, 2.25 mg g^{-1} K₂HPO₄, and 3.8 mg g^{-1} MgSO₄·7H₂O, and placed 274 in a Rapid Automated Bacterial Impedance Technique bioanalyzer (RABIT; 275 Microbiology International Ltd, Frederick, MD, USA), for measuring CO₂ production 276 at room temperature (22 °C). Firstly, we pre-incubated 16 samples from hotspots and 277 bulk soil with and without PHBV amendment for 2 days at 45% water holding 278 capacity (WHC) to minimize the effect of sampling disturbance. To measure 279 280 substrate-induced respiration, a mixture of glucose and nutrients was added and the samples were further incubated for five days at 75% WHC (Blagodatskaya et al., 281 2010; Zhou et al., 2020a). The evolving CO_2 was trapped in a KOH solution where 282 283 the impedance of the solution was continuously measured. The average value of CO₂ emission during the 3 h before and after adding substrates were taken as basal 284 respiration (BR), and substrate-induced growth respiration (SIGR). 285

Microbial respiration in glucose amended soil was used to calculate the following kinetic parameters: the microbial maximal specific growth rate (μ), the growing microbial biomass (GMB) that capable for immediate growth on glucose, the total microbial biomass (TMB) responding by respiration to glucose addition, and the lag period (T_{lag}).

291 Microbial maximal specific growth rate μ was used as an intrinsic property of the 292 microbial population to estimate the prevailing growth strategy of the microbial 293 community. According to Blagodatskaya et al. (2010), higher μ reflects relative 294 domination or shift towards fast-growing *r*-strategists, while lower μ values show relative domination or shift towards slow-growing *K*-strategists.

296 Considering that PHBV is partially soluble in chloroform at 30°C (Jacquel et al., 2007), the microbial biomass we measured by chloroform extraction may not only 298 originate from the soil but also from PHBV degradation. Therefore, microbial 299 biomass C (MBC) was determined using the initial rate of substrate-induced 300 respiration after substrate addition according to the equation of Blagodatskaya et al. 301 (2010):

302 MBC (
$$\mu g g^{-1} \text{ soil}$$
) = ($\mu l CO_2 g^{-1} \text{ soil } h^{-1}$) × 40.04 (2)

303

304 2.7 Soil bacterial community structure

305 2.7.1 Soil genomic DNA extraction, PCR amplification and Illumina sequencing

Total DNA was extracted from 0.5 g soil for each treatment using the Mo Bio 306 PowerSoil DNA isolation kit (Qiagen Inc., Carlsbad, CA, USA) according to the 307 manufacturer's instructions. After extraction, the quality and concentration of DNA 308 were tested using a NanoDrop ND 200 spectrophotometer (Thermo Scientific, USA). 309 According to the concentration, all DNA samples were diluted to 1 ng μ l⁻¹ before PCR 310 amplification. We note that the DNA extracted from Control-hotspots was leaked out 311 312 during shipping for sequencing analysis, and then the concentration of DNA could not reach to the detection threshold. Therefore, the samples from this treatment could not 313 be determined. 314

The V4 and V5 variable region of the bacterial 16S rRNA gene were amplified using the primers 515F (5'-CCATCTCATCCCTGCGTGTCTCCGAC-3') and 907R (5'-CCTATCCCCTGTGTGCCTTGGCAGTC-3'). The polymerase chain reaction (PCR) amplification mixture was prepared with 1 µl purified DNA template (10 ng), 5

 μ l 10 × PCR buffer, 2.25 mmol l⁻¹ MgCl₂, 0.8 mmol l⁻¹ deoxyribonucleotide 319 triphosphate (dNTP), 0.5 μ mol l⁻¹ of each primer, 2.5 U Tag DNA polymerase, and 320 sterile filtered ultraclean water to a final volume of 50 µl. All the reactions were 321 carried out in a PTC-200 thermal cycler (MJ Research Co., NY, USA). The PCR 322 cycles included a 4 min initial denaturation at 94 °C, followed by 30 cycles of 323 denaturation at 94 °C for 1 min, annealing at 53 °C for 30 s, extension at 72 °C for 1 324 min, and a 5-min final elongation step at 72 °C. The PCR products were 325 quality-screened and purified by Qiagen Gel Extraction kit (Qiagen, Hilden, 326 327 Germany). Next, all the amplicons were sequenced on the Illumina Miseq PE250 platform at Novogene Biotech Co., Ltd., Beijing, China. All the sequences have been 328 submit to NCBI SRA data repository under the Accession No. PRJNA648785. 329

330

331 2.7.2 16S gene sequences processing

Briefly, de-noising and chimera analysis conducted with the AmpliconNoise and 332 333 UCHIME algorithms were used to reduce sequence errors (Vargas-Gastelum et al., 334 2015). Furthermore, quality trimming was conducted to remove unwanted sequences shorter than 200 bp and reads containing ambiguous bases and with homopolymers 335 longer than eight bases. The remaining sequences were used to identify the unique 336 sequences by aligning with the SILVA reference database (v.128) (Quast et al., 2013). 337 Within unique sequences, the UCHIME tool was applied to remove chimeras. Then, 338 "Chloroplast", "Mitochondria", or "unknown" were identified and removed from the 339 dataset. Subsequently, after calculating the pairwise distance and generating the 340 distance matrix, a 97% identity threshold was used to cluster sequences into 341 342 Operational Taxonomic Units (OTUs) according to the UCLUST algorithm (Edgar et al., 2011). The most abundant sequence in each OTU was picked as the representative 343

sequence. For each representative sequence, the SILVA reference database (v.128)
was applied to annotate the taxonomic information using RDP classifier algorithm
(Wang et al., 2007).

347

348 2.8 Statistical analysis

The experiment was carried out with four replicates for each parameter. All 349 values presented in the figures are means \pm standard errors of the means (mean \pm SE). 350 The enzyme kinetic parameters (V_{max} and K_m) were fitted via the non-linear regression 351 routine of SigmaPlot (version 12.5; Systat Software, Inc., San Jose, CA, USA). The 352 353 DNA data were rarefied to an equal depth within the minimum observed sample size across all the samples. The following six parameters, namely Richness, Pielou, Chao1, 354 Shannon, Simpson, and abundance-based coverage (ACE), were calculated to 355 describe the alpha diversity of the soil bacterial community based on OTU abundance. 356 The calculation was conducted in QIIME 2 and the illustration was performed by R 357 software (Ver. 3.2) using the packages "ggplot2" and "metacoder". 358

Prior to the analysis of variance (ANOVA), the data were tested for normality (Shapiro-Wilk, p > 0.05) and homogeneity of variance (Levene-test, p > 0.05). Any dataset that was not normally distributed was root square or \log_{10} -transformed to conform with the assumption of normality before further statistical analysis. For alpha diversity index that did not conform to the assumption of normality, the nonparametric Kruskal-Wallis H-Test was applied to determine whether there were significant differences in alpha diversity among different treatments.

367 **3. Results**

368 3.1 Effect of PHBV on plant and soil properties

The mean plant biomass was 0.24 g pot^{-1} without microplastics addition (Table 1). However, PHBV addition ultimately resulted in plant death. PHBV addition greatly increased the soil microbial biomass and dissolved organic C content (p < 0.05, Table 1). MBC and DOC were 12 and 54 times higher in the PHBV-treated than in the control soil, respectively. Additionally, MBN was 45% higher in the PHBV-treatment in comparison to the control, whereas DON decreased by 66% compared to the control soil.

376

377 3.2 Effect of PHBV on soil enzyme activities

378 The maximum potential enzyme activities (V_{max}) were 0.6- and 5-folds higher for β-glucosidase and leucine aminopeptidase in the microplastisphere than in the 379 rhizosphere, respectively (p < 0.05, Fig. 2a, b). Similarly, the substrate affinities (K_m) 380 381 of β -glucosidase and leucine aminopeptidase in the microplastisphere were 1.5-2 times higher in the rhizosphere, respectively (p < 0.05, Fig. 2b, d). The V_{max} and K_m of 382 β -glucosidase and leucine aminopeptidase in microplastisphere were significantly 383 higher compared to those in the PHBV-treated bulk soil (p < 0.05, Fig. 2). In the bulk 384 soil, however, none of the tested enzymes were affected by PHBV addition (p > 0.05, 385 Fig. 2). Furthermore, the V_{max} of β -glucosidase was positively correlated with active 386 microbial biomass ($\mathbb{R}^2 = 0.7$, p < 0.05, Fig. S4). The catalytic efficiency (V_{max} / K_m) of 387 leucine aminopeptidase was higher in the microplastisphere than in the rhizosphere (p 388

< 0.05, Fig. S2c), and the turnover time was approximately 5 times shorter in the microplastisphere than in the rhizosphere soil (Fig. S2d). However, no changes in the catalytic efficiency and turnover time for all the enzymes were found in the bulk soil between the PHBV-treated and control soil (p > 0.05, Fig. S2). Further, the vector angle was lowest in the microplastisphere compared to other soil samples (p < 0.05, Fig. S7d), indicating that microbial metabolisms may be N limited.

395

396 *3.3 Effect of PHBV on soil microbial growth rate*

Different microbial growth patterns in response to substrate addition were observed among hotspots (microplastisphere and rhizosphere) and the bulk soil with and without PHBV addition (Fig. S3). The basal respiration (BR, 45 μ g C g⁻¹ h⁻¹) and substrate-induced growth respiration (SIGR, 58 μ g C g⁻¹ h⁻¹) in the microplastisphere were 10 times and 12 times higher relative to the rhizosphere soil, respectively (Fig. 3a, b). However, the BR and SIGR in the bulk soil were not affected by PHBV addition compared to the control.

Soil respiration showed a clear response to PHBV addition both in the hotspots and in bulk soil (Fig. S3). PHBV addition decreased the maximum specific growth rate (μ) by 22% in the microplastisphere compared to the bulk soil (p < 0.05; Fig. 3c), whereas there was no difference in μ between the microplastisphere and the PHBV-treated bulk soil (p > 0.05). Despite a slower specific growth rate, a 6-fold increase in the fraction of active microbial biomass, and a four times shorter lag period was observed in the microplastisphere vs. rhizosphere soil (Fig. 3d,e,f). *3.4 Effect of PHBV on soil bacterial community composition and diversity*

413	The dominant bacteria phyla were Actinobacteria, Proteobacteria, Acidobacteria,
414	Firmicutes, Bacteroidetes, Chloroflexi, Thaumarchaeota, and Germmatimonadetes in
415	all treatment soils (Fig. 4A), which together encompassed ca. 96-98% of the bacterial
416	reads. Although the dominant phyla in all soils were consistent, changes in the relative
417	abundances of the dominant taxa were observed across the treatments. There was a
418	higher abundance of Proteobacteria and Acidobacteria and a lower abundance of
419	<i>Firmicutes</i> in soils with PHBV addition comparing with control treatment ($p < 0.05$,
420	Fig. 4A). In the family level, the fraction of these 20 dominant families with highest
421	relative abundance decreased after PHBV addition (Fig. 4B). Specifically, the addition
422	of PHBV induced the decrease of Planococcaceae, Xanthomonadaceae, Bacillaceae
423	and the increase of Chitinophagaceae, Comamonadaceae and Oxalobacteraceae (Fig.
424	4B). The detailed family level changes of bulk and hotspot soil bacterial community
425	induced by PHBV addition were also given in Figure 5C. Of the 3800 OTUs detected
426	across all samples, the major numbers of OTUs ($n = 3622$) were shared by
427	control-bulk, PHBV-bulk, and PHBV-hotspots soils, while 54 OTUs were unique to
428	PHBV-hotspots soil and 16 OTUs were unique to the PHBV-bulk soil (Fig. 5A).
429	The mean values for ACE, Chao1, Richness, and Shannon indices in the
430	PHBV-treated bulk soil increased by 10%, 11%, 16%, and 18% relative to the control
431	soil, respectively (Fig. S5), while there were no differences between the
432	microplastisphere and bulk soil after PHBV addition ($p > 0.05$).

434 **4. Discussion**

435 *4.1 Effect of PHBV on plant growth*

PHBV in a polymeric or monomeric state is generally viewed as having very low 436 cytotoxicity (Napathorn, 2014). In all the rhizoboxes added with PHBV, however, all 437 the plants eventually died during the 4-week experiment. This is consistent with 438 previous reports showing that degradation of conventional and bio-based 439 microplastics might negatively affect plant growth when present at high 440 concentrations (Qi et al., 2018; Qi et al., 2020b; Zang et al., 2020). Given that 441 bioplastic polymers are solely composed of C, O and H, it is likely that PHBV 442 addition to soil induced microbial immobilization of essential nutrients (e.g., N, P) 443 444 leading to increased plant stress (Volova et al., 2017; Boots et al., 2019). Such an N immobilization was further confirmed by the decreased DON but increased MBN in 445 PHBV-added soil compared to the unamended control treatment (Table 1). This is 446 447 consistent with Sander (2019) who found that microorganisms on the surface of microplastics need to acquire N from the surrounding soil to fuel growth. It also 448 suggests that PHBV may have stimulated opportunistic plant pathogens (Matavulj et 449 al., 1992), however, more work is required to confirm this. An alternative explanation 450 451 might be that PHBV induced phytotoxicity due to acidification of the soil because of the release of high concentrations of 3-hydroxybutyric acid during PHBV degradation. 452 453 However, this would normally differentially affect root growth rather than shoot growth (Lucas et al., 2008). Further, based on the degradation of other biopolymers 454

(e.g. cellulose, proteins), it is unlikely that an accumulation of the monomer will 455 occur due to rapid microbial consumption (Jan et al., 2009). This is quite likely as it is 456 457 the monomer which is naturally present as a microbial storage compound (Mason-Jones et al. 2019). However, it is possible that undisclosed additives or 458 contaminants in the polymer might also have induced phytotoxicity (Zimmermann et 459 al., 2019). Lastly, we cannot discount other general changes in soil properties and 460 microbial communities following PHBV addition which may also have inhibited plant 461 growth, contributing to plant death (Saarma et al., 2003; Wen et al., 2020). We 462 463 conclude, that contrary to expectation, commercially-sourced PHBV was deleterious to plant growth, at least under higher concentrations of PHBV in the short term, as 464 indicated by the lower seed germination over 7-days germination (Fig. S6). Further 465 466 experiments are therefore needed to determine the mechanistic basis of this response.

467

468 *4.2 Effect of PHBV on soil microbial and enzymatic functional traits*

469 Soil enzyme production is sensitive to both energy and nutrient availability 470 (Allison et al., 2011). This tenet was supported in our study where the input of labile C (i.e. PHBV) increased enzyme activities in hotspots by up to 2 times compared to 471 the bulk soil. This increase in microbial activity is unsurprising given that 472 poly-3-hydroxybutyrate is a common storage compound produced by a wide range of 473 taxonomically different groups of microorganisms, particularly in response to N 474 deficiency and cold stress (Obruca et al., 2016). Consequently, the ability to use 475 PHBV-C is expected to be a widespread trait within the microbial community. For C-476

and N-degrading enzymes, the activity difference between hotspots and the bulk soil 477 was 2-10 times larger when PHBV was added (Fig. 2a, c), demonstrating that 478 479 bioplastic incorporation into the soil directly influences C and N cycling. The higher $V_{\rm max}$ of β -glucosidase in the microplastisphere versus rhizosphere soil can be 480 attributed to the faster growing biomass after PHBV addition (Fig. 3e). This is 481 supported by the positive correlation between our measurement of the active 482 microbial biomass and the V_{max} of β -glucosidase (R² = 0.7, Fig. S4). The increase in 483 β-glucosidase also suggests that PHBV is stimulating the breakdown of other 484 485 common soil polymers (i.e. cellulose). Further, PHBV could be broken down by depolymerases releasing hydroxybutyric acid monomers which fuel the production of 486 energetically expensive exoenzymes (i.e. leucine aminopeptidase; Fig. 2c) capable of 487 488 degrading SOM to acquire N for growth (i.e. positive priming; Zang et al., 2016; Zhou et al., 2020a, b). This was supported by a higher BR and SIGR in the 489 microplastisphere relative to the bulk soil (Fig. 3a, b), as well as the wider ratio of 490 491 DOC and DON in the PHBV-treated soil (294) than in the control soil (1.77) (Table. 1). In accordance with previous studies, N limitation also induced an increase in the 492 catalytic properties (K_a) of leucine aminopeptidase (Song et al., 2020). In line with 493 this, the much shorter turnover time of substrates and higher K_a of leucine 494 aminopeptidase in the microplastisphere was observed compared to the rhizosphere 495 (Fig. S2c,d), which suggests that the community was more limited by N than P in the 496 microplastisphere. This could be supported by lower proportional activity of C- to 497 N-cycling enzymes but higher proportional activity of C- to P-cycling enzymes in the 498

microplastisphere versus the rhizosphere (Fig. S7). The lower vector angle in the 499 microplastisphere further confirmed the microbial metabolisms were likely limited by 500 501 soil N. We therefore hypothesize that due to N limitation the microbial community either (i) changed the intrinsic properties of their hydrolytic enzymes to adapt to the 502 presence of the C-rich bioplastic, and/or (ii) that PHBV induced a shift in the soil 503 microbial community and thus the types of enzymes being produced (Kujur and Patel, 504 2013). Overall, we conclude that N limitation is connected with microbial N 505 immobilization due to stimulated microbial growth after C supply from PHBV 506 507 addition. The C input from the catabolism of PHBV will increase microbial biomass and intensify the N limitation. This was supported by the increased MBC and enzyme 508 activities (especially N related), as well as the shift in enzymatic stoichiometric ratio 509 510 and bacterial community. This contrasts with C hotpots in the rhizosphere, where the supply of C is probably less and where N is also lost from root epidermal cells in the 511 form of amino acids providing a more balanced nutrient supply to the microbial 512 513 community (Jones et al., 2009).

Here we speculate that PHBV breakdown was initially limited by the availability of polyhydroxybutyrate depolymerase (Jendrossek et al., 1993). The abundance and level of expression of this enzyme in soil remains unknown, however, an NCBI search revealed its presence in a wide range of microbial taxa. Although PHB depolymerase may be internally targeted (i.e. to break down internal storage C), there is also a large amount of evidence that it can be externally targeted (i.e. be an exoenzyme; Jendrossek and Handrick, 2002), probably to degrade microbial necromass (Handrick

et al., 2004). Our data support the view that PHBV can be used as a sole C substrate 521 by the bacterial community when supplied exogenously (Martinez-Tobon et al., 2018). 522 523 However, we also observed a significant decrease (22%) in microbial specific growth rate μ in the microplastisphere compared to the rhizosphere, indicating the potential 524 dominance of K-strategy microorganisms. K-strategists typically store more C in their 525 cells and consume it slower (Nguyen and Guckert, 2001), lowering respiration rates. 526 We therefore hypothesize that PHBV degraders break down PHBV exogenously into 527 monomeric units which can then be subsequently transported into the cell where 528 529 re-polymerization into PHB occurs (Shen et al., 2015). Consequently, microbial community structure in the microplastisphere shifted toward species with a lower 530 affinity to oligosaccharides and peptides indicated by a higher $K_{\rm m}$ of β -glucosidase 531 and leucine aminopeptidase. 532

533

534 *4.3. Effect of PHBV on soil bacterial community structure*

535 PHBV addition was associated with an increase in the relative abundance of Acidobacteria and Chloroflexi, and a decrease in the relative abundance of Firmicutes, 536 The latter have previously been described as fast-growing copiotrophs that thrive in 537 environments of high C availability (Cleveland et al., 2007; Jenkins et al., 2010). In 538 contrast, Acidobacteria and Chloroflexi tend to dominate in oligotrophic 539 environments where N availability is low (Ho et al., 2017). Nitrospirae are 540 nitrite-oxidizing bacteria that are ubiquitous in terrestrial environments and that play a 541 major role in biological N cycling and nitrification in agricultural soils (Xia et al., 542

2011). The higher abundance of Nitrospirae after PHBV addition indicated a change 543 in N cycling (Zecchin et al., 2018), which was attributed to greater nutrient limitation 544 545 in the microplastisphere than in the bulk soil (as indicated by V_{max} ratio of C-to-N cycling enzymes; 5.1 vs. 8.6) (Table S1). The relative proportion of Bacteroidetes also 546 increased in the PHBV treatments. These largely copiotrophic organisms are widely 547 distributed in soils, and are considered to be specialized in degrading complex organic 548 matter (Huang et al., 2019). Thus, DOM pools increased in the PHBV-treated soil 549 compared with bulk soil due to the release of monomeric compounds from PHBV 550 551 degradation (Table 1). Although only bacterial communities were investigated in this study, it is likely that fungi and mesofauna populations are also greatly affected by 552 PHBV addition and involved in its degradation. Further studies are required to gain a 553 554 better insight into the complex interactions between these groups. Overall, our results highlight the potential of PHBV to trigger metabolic changes in soil microorganisms 555 (Fig. 6), and thus potentially impact their functional role in soil (Huang et al., 2019). 556 557 In addition to the microplastisphere, PHBV addition also changed the microbial community in the bulk soil, suggesting that these changes are not only confined to 558 hotspots in the soil. 559

560

561 Conclusion

562 Microbial activity in agricultural soil is typically C-limited, such that even small 563 C inputs can induce metabolic changes in the soil microbial community. Here we 564 clearly showed that PHBV addition increased microbial activity, growth, and

exoenzyme activity. This most likely leads to the enhanced mineralization of native 565 SOM by co-metabolism, i.e. microorganisms degrade SOM by using degradable 566 polymers (i.e. hydroxybutyric acid molecules) as an energy source. Remarkably, 567 greater enzyme activity and microbial biomass, and lower affinity for the substrate 568 were observed in the microplastisphere compared to the rhizosphere, indicating a 569 stronger and faster C and nutrient turnover with PHBV addition in hotspots. Taken 570 together, the unique environment may benefit microbial survival in PHBV-treated soil 571 compared with the rhizosphere, possibly altering the soil ecological functions and 572 573 biogeochemical processes, which may result in a stimulation of soil C and nutrients cycling. Although bioplastics have been heralded as a solution to petroleum-based 574 plastics, our research indicates that it is also important to consider the potential 575 576 disbenefits of bioplastics, e.g., for plant growth and health. This is exemplified in the use of plastic microbeads in cosmetics and plastic mulch films in agriculture where 577 the negative environmental consequences were only realized decades after their 578 579 introduction (Sintim and Flurt, 2017; Qi et al., 2020b). Our research was designed to understand the short-term impact of a localized PHBV hotspot in soil. It is clear, 580 however, that longer-term field-scale studies are also required. In-field testing of 581 biodegradation of PHBV under different scenarios (e.g., soil types, agricultural 582 practice, climate changes) as well as using a realistic mixture of polymers over longer 583 periods is therefore required, with particular attention to plant-soil-microbial 584 585 interactions.

Table 1 Plant biomass, microbial biomass carbon (MBC) and nitrogen (MBN), and dissolved organic carbon (DOC) and nitrogen (DON) in untreated soil (Control) and soil to which the bioplastic poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) was added. Values are means (\pm SE) of four replicates. Letters show significant differences between treatments (p < 0.05). MBC was calculated by substrate-induced growth respiration (according to Eqn (8)), MBN, DOC and DON was measured by chloroform-fumigation extraction.

859

Treatment	Plant biomass	MBC	MBN	DOC	DON
	(g DM pot ⁻¹)	(mg kg ⁻¹)			
Control	0.24±0.02	131±23b	20.6±3.4b	163±20b	93.9±5.5a
PHBV	n.d.	1723±625a	30.4±5.6a	9049±889a	32.3±5.2b

860

n.d.: no data due to plant death.

862 **Figure captions**

Fig. 1 Zymograms and hotspots of β -glucosidase (BG), acid phosphatase (ACP) and 863 leucine aminopeptidase (LAP) in untreated soil (Control) and soil to which the 864 bioplastic poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) was added. The 865 color scale bars are proportional to the enzyme activities (nmol cm⁻² h⁻¹). The 866 zymograms are representative of 4 independent replicates. The corresponding area of 867 hotspots relative to the total area of the rhizobox for each enzyme is shown in the 868 right-hand panel. Values are means (± SE) of four replicates. Different letters show 869 significant differences between treatments (p < 0.05). Here, 1, 2, 3 indicate 870 rhizosphere, microplastisphere, and bulk soil. 871

872

Fig. 2 Potential enzyme activities (V_{max}) and substrate affinities (K_m) of β-glucosidase (BG), leucine aminopeptidase (LAP), and acid phosphatase (ACP) in bulk and hotspots in untreated soil (Control) and soil to which the bioplastic poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) was added. Values are means (± SE) of four replicates. Different letters show significant differences between treatments (p < 0.05).

879

Fig. 3 Basal respiration (BR), substrate-induced growth respiration (SIGR), specific growth rate (μ), total microbial biomass (TMB), the fraction of growing microbial biomass to total microbial biomass (GMB/TMB), and their lag time in bulk and hotspots in untreated soil (Control) and soil to which the bioplastic poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) was added. Values are means (\pm SE) of four replicates. Letters show significant differences between treatments (p < 0.05).

887

Fig. 4 Stacked bar chart of the top 10 bacterial phyla with the largest mean relative
abundance in untreated soil (Control-bulk), and bulk (PHBV-bulk) and hotspots
(PHBV-hotspots) soils with the bioplastic poly
(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) addition (A). Stacked bar plot of
the 20 families with largest mean relative abundance in all soil samples (B).

893

Fig. 5 Venn diagram shows shared number of OTUs by untreated soil (Control-bulk), and bulk (PHBV-bulk) and hotspots (PHBV-hotspots) soils with the bioplastic poly (3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV) addition (A). The taxonomical information for each node was given in an individual enlarged heatmap (B). Metacoder heatmap to family level across different treatment. Each node from the center (Kingdom) to outward (Family) represents different taxonomical levels (C). The map is weighted and colored-coded based on read abundance.

901

Fig. 6 Conceptual diagram showing changes of microbial activities and functions in
the hotspots as affected by poly(3-hydroxybutyrate-*co*-3-hydroxyvalerate) (PHBV)
addition. Vertical and horizontal red arrows indicate either an increase or no change of
microbial exoenzyme kinetics and functions in the hotspots compared to the bulk soil,

906 respectively. The red and orange gradient between the panels indicates the decreasing 907 trend in enzyme activity (V_{max}) and substrate affinity (K_m), respectively between the 908 microplastisphere and the rhizosphere. The blue gradient indicates the increasing 909 trend in microbial specific growth rate (μ).
