Lakes are jeopardized by the impacts of climate change on ice seasonality and water temperatures^{1,2}. Yet, historical simulations have not been used to formally attribute observed changes in lake ice and temperature to anthropogenic drivers. Additionally, future projections of these properties are mostly limited to individual lakes or global simulations from single lake models^{3,4}. Here we uncover the human imprint on lakes worldwide using novel hindcasts⁵ and projections from

^{*} corresponding author, email: luke.grant@vub.be

five lake models. Reconstructed trends in lake temperature and ice cover in recent 32 decades are extremely unlikely to be explained by pre-industrial climate variabil-33 ity alone and ice cover trends are consistent with lake model simulations under 34 historical conditions, providing the first formal attribution of lake changes to an-35 thropogenic climate change. Moreover, lake temperature, ice thickness, and ice 36 cover scale robustly with air temperature across future climate scenarios. Impor-37 tantly, the uncertainty in end-of-century impacts is dominated by the choice of 38 emissions scenario rather than lake model or forcing types, showing that lake sys-39 tems will greatly benefit from climate mitigation. Otherwise, these impacts would 40 profoundly alter the functioning of worldwide lake ecosystems and the services 41 they provide. 42

43

Lakes provide ecosystem services to local communities^{6,7} and modulate local climates⁸⁻¹². The seasonality of lake ice cover and lake temperatures are the foundations of the lake environment, controlling many lake processes^{13,14}. In recent decades, lake temperatures have been rising and seasonal ice cover has been declining on regional¹⁵⁻¹⁷ and global scales¹⁻³. Among other things, these changes alter lake stratification, impact lake ecosystem productivity¹⁸ and disturb fisheries^{19,20}.

50

⁵¹ New historical reconstructions of lake ice cover and mixed-layer temperature from the ERA5-⁵² Land reanalysis⁵ provide a high-resolution outlook on these changes in recent decades (Fig. 1a-⁵³ c, Supplementary Fig. 1). From 1981-1990 until 2010-2019, these reconstructions reveal rapid ⁵⁴ changes; 130,472 lake grid cells worldwide have experienced two weeks of lake ice cover loss, ⁵⁵ while on average lakes have lost 9 days of ice cover. Likewise, global-scale reconstructed lake ⁵⁶ mixed layer temperature shows substantial increases, with 64,382 lake grid cells warming more ⁵⁷ than 1.5 °C and a global annual average increase of 0.4 °C (Fig. 2e).

58

While observed and reconstructed changes in lake ice cover and lake temperatures are large, 59 the possibility that they are due to natural climate variability has so far not been ruled out. 60 They have also not been attributed to anthropogenic drivers using formal statistical approaches. 61 Formally, "detection"^{21,22} of climate change impacts consists of showing that observed changes 62 are inconsistent with natural variability by comparing them against simulated variability under 63 human-free climate conditions. Upon successful detection, anthropogenic greenhouse gas emis-64 sions are a plausible candidate to explain ongoing changes in lakes, but this causal link must 65 again be formally established. Such "Attribution"^{21,22} to anthropogenic emissions is achieved 66 by showing consistencies between observed changes and response patterns derived from histor-67 ical climate impact simulations. Together, detection and attribution represent a cornerstone of 68 assessments by the Intergovernmental Panel on Climate Change $(IPCC)^{23,24}$. 69

Climate change detection and attribution We investigate climate change detection and
 attribution in ERA5-Land reconstructed lake variables using two complementary approaches

and novel simulations with five global-scale lake models forced by four global climate mod-72 els (GCMs)²⁵ (see Methods and Supplementary Note 1). The first approach^{26–28} considers a 73 distribution of rank correlations between the multi-model mean of lake simulations forced by 74 GCMs under historical climate forcings (HIST) and a collection of individual pre-industrial 75 control (PIC) lake simulations. This distribution of correlations, assumed to arise from pre-76 industrial climate variability, is compared to the single correlation between HIST and the re-77 constructed time series (OBS for "observations"). Here, detection is inferred by rejecting the 78 null-hypothesis that reconstructed trends are consistent with the distribution of correlations 79 representative of pre-industrial climate variability (correlation-based approach²⁹; Fig. 2a-d). 80 The second approach employs Regularised Optimal Fingerprinting^{21,30}. Here, the slope param-81 eters (henceforth referred to as scaling factors) that scale HIST to fit OBS in a total least-squares 82 regression communicate detection when they are significantly different from 0 (that is, when 83 the 95% confidence intervals of the scaling factors exclude 0). Attribution is achieved when 84 scaling factors additionally overlap with unity. 85

86

Strict attribution to anthropogenic emissions requires both all-forcings historical and natural historical response patterns (including for instance solar and volcanic influences but without anthropogenic emissions). Our experimental framework includes a pre-industrial control instead of a natural historical climate scenario and therefore limits formal attribution to all combined historical forcings (see Methods). However, in light of the dominant role of anthropogenic emissions relative to natural forcings in historical climate change³¹, we argue that any attribution in this framework entails the imprint of human influence.

94

For lake water temperature at 2 m depth (hereafter lake temperature), the correlation-based 95 approach shows a strong distinction between the correlation of OBS and HIST and the distri-96 bution of correlation coefficients of HIST and PIC (Fig. 2a). This implies that lake temperature 97 reconstructions for the recent past lie outside the typical variability of pre-industrial climate 98 and therefore cannot be explained by pre-industrial climate variability (>99% confidence level). 99 For ice onset, break-up, and duration, correlations between OBS and HIST anomalies are again 100 substantially larger than HIST versus PIC correlations (Fig. 2b-d) and also significant (at a 101 confidence level of 95%, 95%, and 99%, respectively). Overall this supports the detection of a 102 climate change signal in lake temperature and all three lake ice indices. 103

104

Scaling factor confidence intervals for lake temperature and all three ice indices are significantly different from 0, confirming the detection of a climate change imprint in all four variables (Fig. 2e-h). For ice onset, break-up and duration, the HIST time series closely resembles OBS, and scaling factors overlap with unity (Fig. 2g-h), providing strong evidence to attribute changes in these variables to external forcings. On the whole, this formal statistical evidence confirms that external forcings - and by extension, anthropogenic emissions - can explain reconstructed changes in lake ice onset, break-up and duration.

Future climate projections Only a few recent studies^{1,3,4} project end-of-century changes in lake temperature and ice cover over large areas under multiple GCM forcings and representative concentration pathways (RCPs), thereby accounting for uncertainties related to meteorological forcing and climate scenario. However, these studies so far disregard both lake model uncertainty and transient lake response to greenhouse gas forcing. Having demonstrated the foregone imprint of climate change on lakes, we project lake temperature and ice conditions across preindustrial to future periods (1661-2099) under RCPs 2.6, 6.0 and 8.5 (see Methods).

119

By the end of the century, annual mean lake temperatures increase and ice cover decreases 120 unanimously under the high-emission scenario RCP 8.5 (Fig. 3a-e). Lakes warm the most (+4-121 $5 \,^{\circ}\text{C}$ by 2070-2099 relative to 1971-2000) in southern temperate latitudes in North America and 122 in temperate latitudes across Eurasia (Fig. 3a, Supplementary Fig. 2-7). In many boreal zones, 123 the June-July-August lake temperature warming exceeds global mean surface air temperature 124 warming by a factor of 1.5-2 (Fig. 3b), indicating a high climate sensitivity for these lakes associ-125 ated with the polar amplification of atmospheric warming. These spatial sensitivity patterns are 126 consistent across RCPs for lake temperature (Supplementary Fig. 8-10), ice thickness (Supple-127 mentary Fig. 11-13) and ice cover indices (Supplementary Fig. 14-16). Ice duration decreases by 128 28-80 days (5th to 95th percentile), with the largest reductions occurring in coastal regions and 129 Scandinavia (> 45 days, Fig. 3e). Ice duration projections are mostly driven by changes in the 130 timing of ice break-up, which happens consistently earlier in the year by the end of the century 131 and agrees with the seasonality of ice thickness losses (Fig. 3c-e, See Supplementary Fig. 17-22). 132 133

In all future scenarios, global mean lake temperatures increase while ice thickness and ice duration decrease (Fig. 4). Multi-model mean projections under RCPs 2.6, 6.0 and 8.5 diverge by 2050 at the latest, with only RCP 2.6 showing an end-of-century stabilization (Fig. 4ac). Global mean projections show high inter-model consistency for all variables, except for ice thickness computed by Community Land Model version 4.5 (See Supplementary Fig. 23-25). By 2100, the scenario spread exceeds the uncertainty originating from the lake models, GCMs and natural variability, underscoring the value of mitigation for avoiding severe lake system changes.

Across all future climate scenarios, multi-model mean lake temperature, ice thickness and ice cover scale robustly with air temperature at the global mean level. Projected average global annual mean scaling for lake temperature, ice duration and ice thickness are $+0.9 \text{ }^{\circ}\text{C}/^{\circ}\text{C}_{air}$, -9.7days/°C_{air} and $-0.033 \text{ m}/^{\circ}\text{C}_{air}$, respectively. RCP 8.5 projections indicate end-of-century global mean anomalies of $+4.0 \text{ }^{\circ}\text{C}$ for lake temperature, -0.17 m for ice thickness and a 46 decrease in days for ice duration.

Discussion Our projections reveal coastal-inland gradients in ice duration projections around northern European and Scandinavian coasts and far eastern and western North America that agree with previous studies³². Large decreases in ice thickness projected in spring months relative to fall months (Supplementary Fig. 17-19) agree with observed changes in lake ice cover ¹⁵² around the northern hemisphere^{16,33,34}. This is also consistent with the dominant contribution ¹⁵³ of earlier ice break-up dates to ice duration changes relative to delayed ice onset (Supplemen-¹⁵⁴ tary Fig. 14-16,20-22), which has been ascribed to a stronger climate change impact on the ¹⁵⁵ spring return of the 0°C isotherm than its fall timing³⁵. At the global mean level, our lake ¹⁵⁶ temperature and ice cover projections for 2100 (Supplementary Fig. 23,25) agree with RCP 2.6 ¹⁵⁷ and 6.0 projections from a single lake model study over a smaller set of lakes³.

158

Challenges to global scale lake modelling arise from parameter value selection, the spatiotem-159 poral coverage and quality of reference products and the selection of adequate impact variables. 160 While anchored to reality through the step-wise bias-correction of their boundary conditions⁵ 161 (see Methods), the lake variables of ERA5-Land are diagnostics and not subject to direct as-162 similation with remote sensing or in-situ data. Furthermore, ERA5-Land provides only mixed 163 layer temperature, which we assume to correspond to 2 m depth to enable comparison with the 164 lake models. While a discrepancy between the global average mixed layer depth of the recon-165 structions and the lake model 2 m depth could invalidate this assumption, it also provides a 166 candidate physical explanation for the positive lake temperature biases precluding attribution 167 of this variable (Supplementary Fig. 26, Fig. 4). Despite these limitations, ERA5-Land is the 168 only available reference product with sufficient spatial and temporal extent to be suitable for 169 detection and attribution purposes. Moreover, a comparison of lake surface temperatures for 272 170 lakes across the globe shows strong agreement between the reconstruction and in situ/remote 171 sensing data (Supplementary Fig. 29), corroborating earlier evaluation efforts and confirming 172 that ERA5-Land can be used as a reference in our study (Supplementary Note 1). Further-173 more, the lake model skill (Supplementary Fig. 27,28, Supplementary Note 2) and inter-model 174 agreement both at the global scale (Supplementary Fig. 23-25) and with respect to latitudinal, 175 coastal and seasonal characteristics (Supplementary Fig. 2-22) adds confidence to the quality of 176 our projections. Future attribution studies may, however, benefit from the ongoing development 177 of global-scale, multi-decade lake temperature and ice cover data sets based on remote sens-178 ing³⁶. As reference data sets and lake models update in the near future, optimal fingerprinting 179 techniques may provide even more robust arguments for detection and attribution. 180

181

In summary, we showed increases in lake temperature and decreases in ice cover with strong 182 inter-model consistency using an ensemble of five global-scale lake models. We demonstrate 183 that reconstructed historical changes in lakes worldwide are *extremely unlikely* to have oc-184 curred due to pre-industrial climate variability alone and attribute their changes in ice cover 185 indices to anthropogenic emissions. Our ensemble framework encompasses climate model, lake 186 model, natural variability and scenario uncertainties, which bolsters our projections and reduces 187 sampling uncertainties in detecting and attributing the anthropogenic signal in historical lake 188 variable changes. These projected changes could have manifold consequences for lake thermal 189 regimes, lake ecological processes and provision of lake ecosystem services. The clear depen-190 dency of our projections on the radiative forcing scenario and the strong arguments we make for 191

¹⁹² reconstructed changes being both unexplainable by pre-industrial climate variability alone and

¹⁹³ consistent with anthropogenic forcings underline the benefit of stabilizing lake systems through

¹⁹⁴ major societal adjustments towards mitigating climate change.

195 Methods

ISIMIP We perform global-scale simulations with five lake models as a part of phase 2b of 196 the Inter-Sectoral Impact Model Intercomparison Project (ISIMIP2b). All simulations adhere 197 to the lake sector protocol (https://www.isimip.org/protocol/#isimip2b), which deter-198 mines simulated periods and scenarios, lake model forcing datasets, the spatial and temporal 199 resolutions of model outputs and lake locations and depths. Pre-industrial control simulations 200 (1661-2099) assume a pre-industrial climate without anthropogenic greenhouse gas forcing²⁵. 201 Historical simulations (1861-2005) use a historical climate, whereas future projections (2006-202 2099) consider RCPs 2.6, 6.0 and 8.5. Four GCMs contributing to phase 5 of the Coupled 203 Model Intercomparison Project (CMIP5) - GFDL-ESM2M, HadGEM2-ES, IPSL-CM5A-LR 204 and MIROC5 - are used as input to the lake models after bias-adjustment to the EWEMBI 205 reference dataset 25,37 . 206

207

The lake models contributing to this study are the Community Land Model version 4.5 (CLM4.5)³⁸, 208 the Arctic Lake Biogeochemistry Model (ALBM)³⁹, SIMSTRAT-UoG⁴⁰, VIC-lake⁴¹ and LAKE⁴². 209 All lake models operate globally at $0.5^{\circ} \times 0.5^{\circ}$ horizontal resolution. Since most real lakes are 210 sub-grid features at this spatial resolution, simulated lake pixels are termed representative 211 lakes in their location. Depth and summed grid-scale area fraction represent those of real lakes 212 contained within the ISIMIP grid cells. Locations and grid-scale fractions of real lakes are de-213 termined by the Global Lakes and Wetlands Database (GLWD)⁴³. All models but CLM4.5 use 214 a $0.5^{\circ} \times 0.5^{\circ}$ lake depth field aggregated from the original 30 arc sec Global Lake Data Base 215 (GLDB)^{44–46}. CLM4.5 lakes are computed with 51-meter depths in each lake containing grid 216 cell. Model characteristics are provided in Supplementary Table 1. 217

ERA5-Land We use ERA5-Land reanalysis lake ice depth and mixed layer temperature 218 reconstructions as reference for lake model evaluation and climate change detection and attri-219 bution⁵. The ERA5-Land product delivers lake variables at 0.1° horizontal and hourly temporal 220 resolution computed by the Fresh-water Lake model (FLake). ERA5-Land is a land-only re-run 221 of ERA5 with a finer resolution for improved application as reference product for land-based 222 energy and water flux studies. The ERA5-Land reanalysis uses lower atmospheric forcing from 223 the ERA5 reanalysis as boundary conditions and is therefore bounded by observations through 224 their assimilation in ERA5. Lake model computations are embedded as a tile in the Tiled 225 ECMWF Scheme for Surface Exchanges over Land incorporating land surface hydrology (HT-226 ESSEL)⁴⁷. Here, lake variables are computed in each grid cell where inland water bodies cover 227 at least 1% of the surface area of the cell. At the time of analysis, this dataset spans 1981 to 228 2019 (inclusive). 220

Data processing Post-processing of model ice thickness outputs was performed to attain
homogenized ice onset, break-up and duration values. Ice cover indices were calculated with
hydrological years, defined as year-long periods which contain ice onset or break-up dates for

lakes in the northern hemisphere. For ice onset calculations, we select the October to September 233 hydrological year and convert each pixel value with ice cover to the day of the year of its time 234 step. After this, we added 365 to periods between 1st January and 30th September so that the 235 days of the year monotonically increase during one hydrological year. A temporal minimum was 236 calculated across this adjusted October 1st (year t), to September 30th, (year t+1 series). This 237 was performed for all available October to September hydrological years in the series, resulting 238 in annual maps of ice start dates. The same process with a temporal maximum calculation across 239 its September to August hydrological year was done for ice break-up calculations, resulting in 240 maps of annual ice end dates. Ice duration is computed as the sum of all "ice-on" days across 241 the October to September hydrological year. We analyze lake temperature at 2 m depth to 242 enable comparison against ERA5-Land mixed layer temperatures and to avoid an overly strong 243 dependence on surface air temperature which can be expected from lake surface temperatures 244 analyses. Global mean calculations on ice thickness datasets include all pixels without ice cover. 245 Reanalysis data are coarsened to the $0.5^{\circ} \times 0.5^{\circ}$ ISIMIP grid. Before calculating spatial means, 246 all data sets are masked for overlapping pixels between lake model simulations and reanalysis 247 data. 248

Detection and Attribution We generate all-forcings response patterns (HIST) by concate-249 nating each ISIMIP lake model's historical time series (1861-2005) with the RCP 8.5 (2006-2099) 250 future simulations to sample forced response patterns for the same period as the ERA5-Land 251 reconstructions (1981-2019; OBS). Next, global annual means are computed from these series, 252 yielding a total of 40 HIST realizations (8 per lake model). For a forced response pattern 253 without human influence (PIC), all available ISIMIP pre-industrial control simulations are con-254 catenated for each lake model and cut into non-overlapping global mean "chunks" matching 255 the time span of the reconstructions. This ideally provides 44 (11×4) chunks of pre-industrial 256 climate variability driven simulations per lake model if pre-industrial control simulations span 257 1661-2099 for each GCM forcing. While some lake models have only computed pre-industrial 258 simulations Reconstructions and response patterns are then computed as anomalies through 259 temporal centering (each series is subtracted by its temporal mean) and applied to two detec-260 tion and attribution approaches; a correlation-based view on detection and Regularised Optimal 261 Fingerprinting (ROF) to confirm detection and attribution. 262

263

The correlation approach (Figure 2a-d), uses all available HIST and PIC anomalies with-264 out smoothing. For each lake variable, Spearman (rank) correlation coefficients are calcu-265 lated between the global annual mean of all available historical simulations (HIST) and ev-266 ery available global annual mean PIC chunk. These correlation coefficients comprise the em-267 pirical distributions in Figure 2. A correlation coefficient is then computed between OBS 268 and the mean of the HIST ensemble, plotted as a red vertical line. A normal distribution 269 $(Z \sim N(mean(corr(PIC, HIST)), std(corr(PIC, HIST))))$ is assumed for reporting the 95% 270 and 99% confidence levels for comparison with OBS-HIST correlation. We use the Spearman 271 correlation coefficient because of its resistance to outliers, however, results are consistent with 272

²⁷³ a Pearson correlation.

274

We use Regularised Optimal Fingerprinting (ROF) with a Total Least-Squares (TLS) regression to compute scaling factors which fit annual mean HIST anomalies (here only the RCP 8.5 versions to avoid artificial consistencies among historical, 1981-2005 sections of anomalies) to reconstructions (OBS) at the global mean level (Figure 2e-h). This follows a generalised linear regression model of the form:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \varepsilon$$

where \mathbf{y} is a vector of n observations (ERA5-Land lake reconstructions; OBS), \mathbf{X} is a matrix 280 of m columns of multi-model mean simulated response patterns (ISIMIP simulations), β is a 281 vector of scaling factors and ε is the regression residual, representing the internal variability in 282 y. We take a single-factor approach; the regression fit is performed for one response pattern at 283 a time (HIST) and therefore X only contains one column or response pattern (m = 1). In a TLS 284 framework, the regression is computed to minimize residuals perpendicular to the best fit line 22 . 285 This addresses uncertainty in **X**, underlining the assumption in TLS that response patterns are 286 not perfectly known. TLS is, therefore, a strong choice for small ensemble study-cases with 287 greater sampling uncertainty, contrasting the Ordinary Least-Squares approach wherein fitting 288 by minimizing vertical residuals assumes the response patterns in \mathbf{X} are perfectly known. The 289 TLS regression is achieved through a singular value decomposition (SVD) on $[\mathbf{y}, \mathbf{X}]$. 290

291

Before the TLS fit, observations and response patterns are converted to 5-year block means, 292 temporally centered (subtracted by their mean) and pre-whitened. Pre-whitening to achieve 293 unit noise is the "optimization" of signals in ROF. This is done with a regularised covariance 294 matrix, \widehat{C}_1 , which represents internal variability in our lake variables. \widehat{C}_1 is derived from one 295 of two covariance estimates, C_1 and C_2 , computed from equal-sized samples of available PIC 296 chunks. Key to ROF, regularisation involves conforming \widehat{C}_1 to equal $\lambda C_1 + \rho I$. Here, I is 297 the identity matrix, and λ and ρ are coefficients whose estimators are provided by Ledoit and 298 Wolf⁴⁸. This avoids underestimating the lowest eigenvalues of \widehat{C}_1 , which translates to a conser-299 vative estimate of noise³⁰. C_2 is used for calculating the confidence intervals on scaling factors 300 and performing a residual consistency test (RCT). Final computations of scaling factors, their 301 confidence intervals and RCTs are taken as the median of 1000 realizations of ROF through 302 shuffling the PIC chunks from which C_1 and C_2 are computed²⁸. 303

304

The RCT validates the residuals in the TLS regression against the assumed internal variability³⁰. Here, C_2 and **X** are used in Monte Carlo simulations to bootstrap 1000 samples of virtual observations, fingerprints and covariance matrices assuming a perfect fit with $\beta = 1$. The smallest squared singular value (or eigenvalue, λ) of the SVD in the original TLS fit - representing the residuals in the regression - is then corrected and used as a test statistic against 1000 virtual eigenvalues ($\lambda_{\text{virt,i=1,...1000}}$) and their kernel density estimates (i.e λ is tested against 1000 virtual, empirical distributions). The RCT is passed if λ is consistent with these distributions, which is considered true if the average position of λ in the virtual distributions yields a p-value greater than 0.10 (see Supplementary Note 3).

Future projections We calculate all maps as signals across 1971-2000 and 2070-2099 mean baseline and future periods. For scaling, each signal map is first divided by the change in global mean air temperature for the same period before calculating ensemble means. For each GCM-Lake model combination, we compute global mean anomalies relative to the global temporal average of the pre-industrial control simulation (Fig. 4). Global mean air temperature series from GCMs are treated the same. In panels d, e and f of figure 4, series are smoothed with a 21-year running mean to reduce natural variability effects.

Data Availability The ISIMIP2b lake sector simulations presented in this study are avail-321 able through the Earth System Grid Federation (ESGF, https://esgf-data.dkrz.de/). The 322 ERA5-Land lake data used in this study are developed by the European Centre for Medium-323 Range Weather Forecasts (ECMWF) and are available through the Copernicus Climate Change 324 Service's Climate Data Store (CDS, https://cds.climate.copernicus.eu/cdsapp#!/search? 325 type=dataset). The observed lake surface temperatures used for validating ERA5-Land can be 326 found here https://portal.lternet.edu/nis/mapbrowse?packageid=knb-lter-ntl.10001. 327 3. 328

Code Availability All codes used to generate the analyses are available through the github repository of the Department of Hydrology and Hydraulic Engineering at VUB (https:// github.com/VUB-HYDR/2020_Grant_etal).

Acknowledgements We are grateful to the Potsdam Institute for Climate Impact Research 450 (PIK) for initiating and coordinating the ISIMIP initiative, with special thanks to Matthias 451 Büchner for his oversight of ISIMIP data publishing, and to the modelling centres for making 452 their impact simulations publicly available through ESGF. We owe many thanks to Friederike 453 Fröb and Alexander Winkler for sharing their Regularised Optimal Fingerprinting python code, 454 and to Martin Schmid for the helpful discussions. We also thank the National Center for Atmo-455 spheric Research (NCAR) for maintaining CLM and making the source code publicly available. 456 I.V. is a research fellow at the Research Foundation Flanders (FWO) (FWOTM920). W.T. 457 acknowledges the Uniscientia Foundation and the ETH Zurich Foundation for their support to 458 this research. Z.T. is supported by the U.S. DOE's Earth System Modeling program through the 459 Energy Exascale Earth System Model (E3SM) project. The computational resources and ser-460 vices used in this work were provided by the VSC (Flemish Supercomputer Center), funded by 461 the Research Foundation - Flanders (FWO) and the Flemish Government – department EWI. 462 R.M participated trough the project WATExR of the JPI Climate ERA4CS Program, and ac-463 knowledges funding from the CERCA program of the Generalitat de Catalunya. V.M.S. and 464 A.V.D. used the resources of Moscow State University Supercomputer Center ("Lomonosov-2" 465 supercomputer). 466

Author Contributions L.Gr., I.V. and W.T. designed the study. L.Gr. wrote the manuscript
with support from all authors and performed all analyses under the supervision of I.V. and
W.T.. L.Gu. provided guidance on the detection analysis. Z.T., M.P., V.M.S., A.V.D., B.D.,
A.B.G.J., S.I.S. and W.T. conducted the global lake model simulations. J.S., F.Z., M.G., D.P.,
R.M. and W.T. coordinated the ISIMIP lake sector activities.

472 Author Information The authors declare no Competing Interests.

Figure 1: **Reconstructed historical lake ice changes.** Changes in ice onset (**a**), ice break-up (**b**) and ice duration (**c**) in 40 years across baseline (1981-1990) and recent (2010-2019) periods as obtained from ERA5-Land.

Figure 2: Detection and attribution of the human imprint on lake variables. Empirical distribution of Spearman correlation coefficients between all available PIC chunks (realizations of pre-industrial climate variability selected across 1661-2099) and the HIST response pattern (the multi-model mean historical realization) for lake temperature (**a**), ice onset (**b**), ice break-up (**c**) and ice duration (**d**). Red lines show the correlation coefficient between the HIST series and OBS (ERA5-Land reconstructions). Vertical blue lines mark the 95% and 99% cumulative probability of an assumed normal distribution for the sample of PIC-HIST coefficients. Global multi-model mean time series for HIST and PIC forced response patterns and OBS smoothed by a 5-year running mean for lake temperature (**e**), ice onset (**f**), ice break-up (**g**) and ice duration (**h**). Results of single-factor ROF output on HIST are displayed in insets. Here, scaling factor confidence intervals denote their 0.5-99.5% uncertainty range and infer detection when excluding the 0 line. Attribution is achieved when confidence intervals additionally include unity.

Figure 3: End-of-century change in lake temperature and ice onset, break-up and duration according to RCP 8.5. a, Multi-model mean change in annual lake temperatures for Y projections with X lake models at 2 m depth. b, the mean June-July-August lake temperature change at 2 m depth divided by the change in same-year global mean surface air temperature. c, d e, changes in ice onset, break-up and duration, respectively. All results compare end-of-century (2070-2099) to present-day (1971-2000) conditions.

Figure 4: Anomalies for lake temperature, ice thickness and ice cover. a, Multi-model mean anomaly time series of annual lake temperatures, b, ice thickness and c, ice cover duration. Uncertainty bands in panels a, b and c represent +/-1 standard deviation in lake model ensemble projections. In panels d, e and f the same lake variable anomalies are scaled against surface air temperature anomalies, with uncertainty bands representing the full range of scaled projections.
