15 **Abstract**

16 Empirical evidence for the positive relationship between tree species richness and
17 wood decomposition is weak, despite the greater numbers of decomposers in diverse
18 stands. Tree species identity affects decomposition rates strongly by altering soil
19 communities and micro-environments. It is therefore likely that tree species richness
20 influences spatial variation rather than the mean rate of decomposition. We used a
21 neighbourhood approach to test this hypothesis by quantifying decomposition rates
22 and decomposer activities within deadwood, whilst measuring the surrounding micro-
23 environments.

24 Using the BEF-China experimental platform, we placed three fine branches from
25 seven tree species across richness gradients for one and two years. As expected, plot
26 species richness increased the spatial variation of wood decomposition of three
27 species but decreased the mean rate of wood decomposition of two species.

28 Neighbourhood trees altered wood decomposition in two ways. First, increasing
29 amounts of leaf tannins reduced termite activities and the number of fungal
30 fruitbodies. Second, higher species richness increased tree volumes and thus cooled
31 the understory, which reduced the occurrence and feeding intensity of ectothermic
32 termites. Neighbourhood species richness showed positive effects on decomposer
33 activities (i.e. termite occurrence, fruitbody number and mycelium cover) after two
34 years, probably by weakening resource limitation of deadwood biomass and
35 increasing the stages of decay. Neighbourhood metrics had comparable (after 1 year)
36 and even stronger effects (after 2 years) on decomposer activities than wood traits.

37 Our study reveals that tree species richness promotes spatial variation in wood

38 decomposition rates by enhancing environmental heterogeneity. Our results explain
39 how young regenerating species-rich forests, where termites are the dominant
40 decomposers, can maintain deadwood stocks and decomposer activities over
41 relatively longer time spans.

43

44 **1. Introduction**

45 Decomposition is central to ecosystem functioning, with ~ 90% of global
46 terrestrial plant production entering the dead organic matter pool (Cebrian, 1999).
47 One of the main drivers of decomposition is the diversity of living trees, which
48 represents the main source of litter in forests (Cardinale et al., 2011). Tree species
49 diversity is linked to decomposition rates because distinct litter traits among tree
50 species attract decomposers with specific needs, leading to complementary resource
51 use and facilitation among decomposers (Gessner et al., 2010; Austin et al., 2014).
52 However, multi-site experiments find weak and even neutral effects of tree species
53 richness on litter decomposition rates (Desie et al., 2023), especially for deadwood
54 (Eichenberg et al., 2017; Joly et al., 2017; Pietsch et al., 2019).

55 As opposed to tree species richness, tree species identity has been shown to exert
56 strong effects on decomposition rates (Vivanco and Austin, 2008; Desie et al., 2023),
57 for example the ‘home-field advantage’ describes the rapid decomposition of litter in
58 the vicinity of conspecifics (Purahong et al., 2019; Fanin et al., 2021). This effect is
59 due to the plant-soil feedbacks that shape distinct soil communities and micro-
60 environments under different tree species. For example, the dissimilarities of soil
61 fungal communities (viz. saprotrophs, plant pathogens, and ectomycorrhizal fungi)
62 increased significantly with woody plant phylogenetic distance in five mountain
63 forests of eastern China (Yang et al., 2019). Moreover, more recalcitrant litters (Joly et
64 al., 2017) and stronger shading (i.e. cooling) effects (Gottschall et al., 2019) of certain
65 tree species could decelerate decomposition rates.

66 Logically, tree species richness is more likely than tree species identity to

67 diversify decomposition rates by creating micro-sites of distinct environmental
68 conditions that alter the decomposing activities of soil communities. Indeed, the
69 spatial variation of wood decomposition rates at local scales are considerable, with
70 climate explaining only 28% of the variation in decomposition in one cross-site study
71 (Bradford et al., 2014). In the meantime, high within-site replications and
72 measurements of regulatory factors at the same spatial grain have been advocated to
73 capture the spatial variation in decomposition rates (Bradford et al., 2016). We
74 therefore set out to investigate how tree species richness causes spatial variation in
75 wood decomposition rates, using a neighbourhood approach for each within-site
76 replicate, i.e. measuring decomposer activities within and micro-environments around
77 deadwood.

78 Termites and fungi are the major decomposers of deadwood in subtropical and
79 tropical forests (Bradford et al., 2014; Ulyshen, 2016), meaning that rates of
80 decomposition should be positively correlated with termite occurrence (Wu et al.,
81 2020) and fungal fruitbody production (Raudaskoski and Salonen, 1984; K ues and
82 Liu, 2000). Neighbourhood trees could affect termites' and fungal activities by
83 modifying the understory environment, e.g. shedding leaves with distinct physico-
84 chemical properties, and creating differing levels of shade depending on the size and
85 species identity of trees (Wu et al., 2020, Wu et al., 2021b). Therefore, quantifying
86 functional trait means, total tree volume and species richness of neighbourhood trees
87 could better predict decomposer activities and decomposition rates.

88 If stand-level tree species richness increases the mean rates of wood
89 decomposition, we should observe positive effects of neighbourhood (i.e. 3×3 tree

90 grid surrounding wood samples) species richness on decomposer activities which in
91 turn promote wood decomposition. Moreover, if stand-level tree species richness
92 increases the spatial variation of wood decomposition rates, we should observe
93 significant effects of the environmental modifications by neighbourhood trees on
94 decomposer activities and decomposition rates. Our experiments were based on the
95 observation that wood traits and species identity substantially alter decomposition rate
96 (van Geffen et al., 2010; Hu et al., 2018) and its dominant drivers (Wu et al., 2021a).
97 By using fine branches of seven tree species as substrates, our experimental design
98 allowed us to assess the relative contribution of neighbourhood metrics on
99 decomposer activities and wood decomposition rates by comparing the standardised
100 effect size with that of wood traits.

101 **2. Material and methods**

102 **2.1 Study site and plot species richness**

103 The study was conducted in the BEF-China experimental platform in Jiangxi
104 Province, China (29.08°-29.11°N, 117.90°-117.93°E). The local climate is
105 subtropical, with mean annual temperature and precipitation of 16.7°C and 1800 mm.
106 A large-scale tree biodiversity experiment was initiated in 2009-2010 at two study
107 sites (A and B) of approximately 20 ha each. Each plot is 25.8 m × 25.8 m in size and
108 planted with 400 individual trees arranged on rectangular 20 × 20 grids with 1.29 m
109 spacing between rows and columns. Plots were established adjacent to each other,
110 forming a continuous cover across the entire site. Undesired herbs and woody species
111 were removed from all plots annually. The composition of tree species for each
112 richness gradient has been introduced in detail (Bruehlheide et al., 2014). We selected

113 134 plots that spanned the study sites (Fig. S1), including 54 monocultures, 42 two-
114 species mixtures, 21 four-species mixtures, 11 eight-species mixtures, four 16-species
115 mixtures and two 24-species mixture plots. Given that decomposition experiments
116 were conducted in the central grid of 6×6 trees, we defined plot species richness as
117 the number of tree species within the central grid. Plot species richness ranged from 1
118 to 15. Number of trees per plot ranged from 108 to 400. Mean tree height (basal
119 diameter) ranged from 0.12 m (0.27 cm) to 8.09 m (7.92 cm). Terrain slope ranged
120 from 14.37° to 43.85° .

121 **2.2 Decomposition experiment**

122 Seven tree species were chosen for the decomposition experiments: *Alniphyllum*
123 *fortunei*, *Myrica rubra*, *Schima superba*, *Quercus serrata*, *Cunninghamia lanceolata*,
124 *Platycarya strobilacea*, and *Castanopsis eyrei*. These species vary in wood density,
125 C:N ratios, tannin content and lignin content (Table S1) and are widespread in
126 southeast China (Wu et al., 2021b). Lignin content (%) was measured using near-
127 infrared reflectance spectroscopy (Tsuchikawa and Kobori, 2015); tannin content
128 (mostly condensed tannin; mg/g) by the radial diffusion method (Hagerman, 1988);
129 C:N ratio by a CHNS-932 elemental analyzer (LECO Corporation, St. Joseph, MI,
130 USA).

131 Healthy branches (length = 20.3 ± 0.6 cm; diameter = 1.5 ± 0.3 cm) were
132 collected from living trees around the study sites in December 2014. Bark traits are
133 different from wood tissue (Li et al., 2021) and pose distinct effects on wood
134 decomposition rates across tree species (Dossa et al., 2018; Tuo et al., 2021).
135 Therefore, we removed bark to focus on wood decomposition. Meanwhile, cut

136 surfaces on both ends of the samples were sealed with silicone to ensure that
137 decomposers could only enter samples radially. This is because decomposers such as
138 termites entering cut ends might show no sign on the radial surface and therefore the
139 level of decomposer activities would be difficult to assess (see next section for
140 details). 35 samples per species were dried to constant weight for > 48 h at 60 °C, and
141 dry matter content was averaged for each species. The initial dry mass of field
142 samples was estimated by multiplying fresh mass with species-specific dry matter
143 content. Sample volumes were calculated as the cylinder, with diameter averaged
144 from two measurements at both ends of the sample. Wood density was calculated as
145 initial dry mass divided by sample volume.

146 Each sample was enclosed in a 5 mm mesh bag. Samples of seven species were
147 joined together as a bundle using cable ties. Six bundles were placed at the base of six
148 trees along the diagonal in each plot's central grid of 6 × 6 trees (Fig. S2). Having
149 placed 5628 samples (7 species × 6 bundles × 134 plots) in January 2015, we
150 retrieved half after one year (1st, 3rd and 5th bundle per plot) and half after two years
151 (2nd, 4th and 6th bundle per plot). After removing fungal fruitbodies and soil
152 transported by termites, samples were dried at 60 °C until we observed no further loss
153 of weight. Wood mass loss was calculated as the ratio of dry mass loss to the initial
154 dry mass.

155 **2.3 Decomposer activity**

156 Previous studies confirmed that termites are the dominant invertebrate
157 decomposers of deadwood in the BEF-China experimental platform (Eichenberg et
158 al., 2017). We recorded the occurrence (0/1) of termites within samples as the first

159 measure of termite activities. In addition, the feeding intensity of termites was also
160 documented to estimate the level of termite-mediated decomposition. Termite feeding
161 was evidenced by soil sheeting and bore holes on the surface of deadwood as well as
162 soil and complex tunnels and galleries inside deadwood (Fig. S3). To determine
163 termite feeding intensity, one person visually inspected the surface of each sample for
164 boreholes (Liu et al., 2015; Cheesman et al., 2018), and then rated them using six
165 predefined area percentage classes (estimated as 0, < 5, < 10, < 25, < 50, > 50), with
166 the respective levels (n = 0, 1, 2, 3, 4, 5) used in the analysis.

167 Wood-decomposing fungi exploit resources through vegetative growth, i.e.
168 mycelium (Baldrian, 2017). Before fruiting for spore dispersal, mycelium must reach
169 a critical biomass which serves fruitbody production (Raudaskoski and Salonen,
170 1984; Kües and Liu, 2000). Therefore, we used mycelium cover and fruitbody
171 number as the indicator of fungal-mediated decomposition. Mycelium cover on the
172 wood surface was visually inspected and rated into six levels as with termite feeding
173 intensity. The number of fruitbodies with clear boundaries was visually counted. In
174 cases where fruitbodies formed conglomerations (e.g. *Trametes*), we treated each
175 basidiocarp as a separate fruitbody because it could produce and disperse its own
176 spores.

177 **2.4 Neighbourhood metrics**

178 The neighbourhood trees were defined as the grid of 3×3 trees surrounding the
179 bundle of wood samples (Fig. S2a). Neighbourhood species richness ranged from 0 to
180 6 (Fig. S4a). Death of some trees meant that there were no neighbourhood trees for
181 some bundles and so the analyses for neighbourhood effects excluded these samples.

182 We calculated the abundance-weighted mean of three plant traits (measured on fresh
183 material) at the neighbourhood level, including wood density (g/cm^3), leaf nitrogen
184 content (mg/g) and leaf tannin content (mg/g). These traits could impact the
185 decomposing activities of termites and fungi mechanically through wood density (Liu
186 et al., 2015; Wu et al., 2020), nutritionally through leaf nitrogen content (Allison et
187 al., 2009; Mullins et al., 2021) and physiologically through leaf tannin content
188 (Scalbert, 1991; Ismayati et al., 2018). We therefore used neighbourhood mean trait
189 values to indicate the overall palatability of fallen branches and leaf-litter. Species-
190 level trait data was accessed from existing datasets (Eichenberg et al., 2016a, 2016b)
191 to calculate the neighbourhood means (Fig. S5).

192 Individual tree volume proxies (dm^3) were calculated as $H \times \pi(\text{BR})^2$ in which H
193 was height and BR was basal radius at the ground level. These volume proxies were
194 transformed to more accurate tree volume estimates by multiplying the proxies with a
195 size-dependent correction factor estimated and applied by a previous study (Huang et
196 al., 2018). Individual tree data (H and BR) recorded in 2014 were used to estimate
197 total tree volumes at neighbourhood (Fig. S4b) and plot levels. To quantify the
198 cooling effects of total tree volume, we monitored air temperature at 30-minute
199 intervals during the first year (2014-2015) with HOBO U23 Pro V2 data loggers
200 (Onset Computer Corporation, Bourne, MA, USA). Aluminum panels placed ca. 5 cm
201 above the loggers protected them from direct sunlight, rain, and wind turbulence. One
202 logger per plot was placed between the 11th and 12th row and column of trees (Fig.
203 S2). Mean annual temperatures were calculated and analyzed for relationships with
204 total tree volume.

205 **2.5 Statistical analysis**

206 All statistical analyses were conducted in R version 4.0.5 (R Core Team, 2021).
207 We conducted analyses at two spatial scales. At the plot scale, we fitted simple linear
208 regression models to test if plot species richness increased the mean or spatial
209 variation of wood mass loss for each of seven tree species. The spatial variation was
210 estimated as the coefficient of variation ($CV = \text{standard deviation} / \text{mean} \times 100\%$) of
211 wood mass loss, which could control for the vast difference in wood mass loss among
212 species and across plots. Furthermore, we tested if tree species richness increased total
213 tree volume (Huang et al., 2018), which in turn can reduce air temperature (de Frenne
214 et al., 2019). This analysis was also applied at the neighbourhood scale.

215 At the neighbourhood scale, we fitted linear mixed models with R package '*lme4*'
216 (Bates et al., 2015) to test if neighbourhood species richness increased wood mass
217 loss for each of the seven tree species, with plot identity as random effect. We then
218 fitted bivariate generalised linear mixed models for wood mass loss (Gaussian),
219 termite occurrence (Binomial) and fruitbody number (Poisson) to test if they were
220 significantly related to five wood traits (diameter/density/C:N ratio/tannin/lignin) and
221 five neighbourhood metrics (richness.n/volume.n/density.n/nitrogen.n/tannin.n). The
222 ten predictors were scaled (mean = 0; standard deviation = 1) so that their parameter
223 estimates were comparable. Species identity of wood samples and plot identity were
224 treated as random effects. We fitted cumulative link mixed models with R package
225 '*ordinal*' (Christensen, 2022) for termite feeding intensity and fungal mycelium cover
226 since they were ordinal data. The highest log-likelihood was reached when the
227 threshold structure was set as 'flexible', and the link function as 'cloglog' and 'logit'

228 for 1-year and 2-year models, respectively. We also fitted mixed models to test if
229 environmental predictors at coarser scale (study site/air temperature/plot species
230 richness) significantly impacted wood mass loss and decomposer activities, by
231 treating plot identity and species identity as random effects.

232 Finally, we fitted piecewise structural equation models with R package
233 '*piecewiseSEM*' (Lefcheck, 2016) to test the potential paths from five wood traits and
234 five neighbourhood metrics, via termite occurrence and fruitbody number, to wood
235 mass loss. Previous studies have confirmed that termite feeding could alter fungal
236 activities (Wu et al., 2020; Bradford et al., 2021), and we thus tested if termite
237 occurrence significantly impacted fruitbody number. Instead of assuming an *a priori*
238 full path model, we first ran a backward stepwise selection to remove variables of
239 little importance. R package '*lmerTest*' (Kuznetsova et al., 2017) and
240 '*StatisticalModels*' (Newbold, 2021) were used for variable selection of gaussian and
241 non-gaussian mixed models, respectively. The remaining variables for each response
242 were the input for *piecewiseSEM* analyses. Apart from the causal paths, we added the
243 correlative path between neighbourhood species richness and total tree volume (Kunz
244 et al., 2019). We used Shipley's d-separation test to evaluate model fit through
245 Fisher's C statistic and χ^2 -based *p*-value (Shipley, 2013). We refined the initial model
246 by dropping non-significant paths or including missing paths that were significant,
247 until the decrease in AICc (i.e. Δ AICc) was less than 2 units. See Table S2 for model
248 selection and see Table S3-S4 for model summaries.

249 **3. Results**

250 We successfully retrieved complete samples from 134 plots after one year, and

251 from 126 plots after two years. Mean wood mass loss across the seven species was
252 $46.6\% \pm 23.8\%$ after one year, and $71.7\% \pm 25.0\%$ after two years.

253 **3.1 Does plot species richness increase the mean or spatial variation of wood** 254 **mass loss?**

255 Based on simple linear regressions (Fig. 1), we found negative effects of plot
256 species richness on mean wood mass loss of two species (*A. fortunei* and *Q. serrata*),
257 and positive effects on the coefficient of variation (CV%) of three species (*A. fortunei*,
258 *Q. serrata* and *S. superba*). Results for the other species were insignificant ($p \geq 0.1$).
259 Mixed models pooling all seven species (Table 1 and Table S5) showed that plot
260 species richness had insignificant effects on wood mass loss and decomposer
261 activities.

262 **3.2 Does neighbourhood species richness drive wood mass loss via decomposer** 263 **activities?**

264 Bivariate linear mixed models at the sample-level (Fig. 2) showed that
265 neighbourhood species richness had negative relationships with wood mass loss of
266 three species (*A. fortunei*, *C. eyrei* and *S. superba*). Results for the other species were
267 insignificant ($p \geq 0.1$). Similar results were found after pooling seven tree species
268 (Fig. 3), namely that neighbourhood species richness significantly ($p \leq 0.05$) and
269 marginally significantly ($0.05 < p < 0.1$) decreased wood mass loss after one year and
270 two years, respectively.

271 Unexpectedly, neighbourhood species richness did not increase decomposer
272 activities after one year but after two years (Fig. 3 and Fig. S6). Bivariate models
273 showed that after one year of decomposition, there were significant negative effects of

274 neighbourhood species richness on fruitbody number but not on other metrics of
275 decomposer activities. After two years of decomposition, we found positive effects of
276 neighbourhood species richness on termite occurrence ($p = 0.010$) and fungal
277 mycelium cover ($p = 0.069$) and found no significant effects on other metrics of
278 decomposer activities. By incorporating all causal paths, *piecewiseSEM* models
279 further showed that neighbourhood species richness had direct positive effects on
280 fruitbody number after two years, which was neutralized by the indirect negative
281 effects through increasing termite occurrence and the negative interactions between
282 termites and fungi (Fig. 4b).

283 Bivariate linear mixed models (Table 2) showed that termites predominantly
284 drove wood mass loss. After one year of decomposition, both termite occurrence and
285 termite feeding intensity significantly increased wood mass loss, while fungal effects
286 were insignificant. After two years of decomposition, termite feeding intensity
287 increased wood mass loss significantly whereas termite occurrence had no significant
288 effects. In contrast, both fungal fruitbody number and mycelium cover showed
289 significant negative relationships with wood mass loss.

290 **3.3 How do neighbourhood metrics alter decomposer activities and wood mass** 291 **loss?**

292 Besides species richness, three neighbourhood metrics showed impacts on
293 decomposer activities and wood mass loss, including total tree volume ('Volume.n'),
294 mean leaf tannin content ('Tannin.n') and mean wood density ('Density.n'). Although
295 wood traits exerted stronger effects on wood mass loss, neighbourhood metrics
296 exerted comparable and even stronger effects on decomposer activities (Fig. 3 and

297 Fig. S6).

298 Bivariate mixed models showed that Volume.n negatively affected termite
299 occurrence after one year ($p = 0.054$) but positively affected fruitbody number after
300 two years ($p < 0.001$; Fig. 3). The *piecewiseSEM* analyses showed that Volume.n
301 indirectly decelerated wood mass loss after one year by decreasing termite occurrence
302 (Fig. 4a). Similarly, Volume.n showed an indirect negative relationship with wood
303 mass loss after two years, which was mediated by the increase of fruitbody number
304 and its negative correlation with wood mass loss (Fig. 4b). Further analyses revealed
305 that neighbourhood species richness increased Volume.n, which in turn decreased air
306 temperature (Fig. 5 and Table S6). Mixed models at the sample-level (Table 1 and
307 Table S5) showed that temperature increased termite occurrence after one year ($p =$
308 0.006), and increased termite feeding intensity ($p = 0.063$) and wood mass loss after
309 two years ($p = 0.002$). In contrast, temperature showed negative relationships with
310 fungal mycelium cover after two years ($p = 0.003$).

311 Bivariate mixed models (Fig. 3) showed that Tannin.n had negative effects on
312 wood mass loss ($p = 0.070$), termite feeding intensity ($p = 0.066$; Fig. S6) and
313 fruitbody number ($p < 0.001$) after one year, and had significantly negative effects on
314 termite occurrence and fruitbody number after two years. The *piecewiseSEM* analyses
315 did not report direct or indirect effects of Tannin.n on wood mass loss but confirmed
316 that Tannin.n negatively impacted fruitbody number after one year (Fig. 4a), and
317 termite occurrence and fruitbody number after two years (Fig. 4b).

318 Bivariate mixed models (Fig. 3) showed that Density.n had significant negative
319 relationships with wood mass loss after two years. Density.n also had significant

320 positive relationships with fruitbody number at both time-steps, which was supported
321 by the *piecewiseSEM* analyses (Fig. 4). Accordingly, we found that deadwood density
322 decreased wood mass loss at both time-steps (Fig. 3). Meanwhile, deadwood density
323 showed significant positive relationships with fruitbody number and mycelium cover
324 at both time-steps, except that fruitbody number after two years decreased with higher
325 deadwood density (Fig. 3f). Although we did not find significant relationships
326 between Density.n and termite activity, we found significant negative effects of
327 deadwood density on termite feeding intensity (Fig. S6a).

328 **4. Discussion**

329 **4.1 Tree species richness decreases wood decomposition rate**

330 Theoretically, increasing tree species richness should strengthen complementary
331 resource use and facilitation among different decomposers, thus increase
332 decomposition rate (Gessner et al., 2010). On the contrary, we observed negative
333 effects of tree species richness on wood mass loss of four tree species at the plot scale
334 and at the neighbourhood scale. Greater wood volume production and crown
335 complementarity in the species-rich neighbourhood (Kunz et al., 2019) exert stronger
336 cooling effects on the understory microclimate (de Frenne et al., 2019). Termites are
337 ectothermic and their wood consumption rates generally scale with temperature
338 (Gautam and Henderson, 2011; Griffiths et al., 2021). Accordingly, we found negative
339 effects of total tree volume and positive effects of mean air temperature on termite
340 activities, meaning that the ‘Richness-Volume-Temperature’ pathway could be an
341 important mechanism reducing wood decomposition rates in young regenerating
342 forests. Furthermore, increasing tree volume reduced maximum temperature but

343 increased minimum temperature (Fig. S9), which in turn reduced termite feeding
344 activity (Table S7). While reduction in maximum temperature could depress termite
345 activities due to their ectothermic and metabolic-driven nature, we posit that
346 increasing minimum temperature might release the overwintering termites
347 (*Reticulitermes* for most specimens discovered), which would have dwelled in and fed
348 on branch samples at low temperature (Hu and Song, 2014). Our study therefore
349 suggests that in young regenerating species-rich forests, where termites are dominant
350 decomposers, deadwood accumulation is greater (Liu et al., 2018) not only because of
351 biomass production (Huang et al., 2018), but also because of slower wood
352 decomposition.

353 Other mechanisms which are not covered in this study could contribute to the
354 negative effects of tree species richness on termite activities and wood decomposition.
355 First, the top-down control of decomposers by predators directly affects
356 decomposition rates (Gessner et al., 2010). Ants are widespread and efficient
357 predators of termites (Tuma et al., 2020). Previous studies in the BEF-China
358 experimental platform found that leaf-litter ant species richness increased with plot
359 tree species richness (Skarbek et al., 2020). Predatory ant species richness increased
360 with canopy density, lowering termite abundance (Wu et al., 2021b). Second, the
361 amount of surrounding deadwood could also play a role. We found that termite
362 occurrence (Fig. 3) and feeding intensity (Fig. S6) increased with wood diameter,
363 indicating that larger pieces of wood attract more termites than smaller pieces.
364 Termites would therefore be less likely to discover small pieces of deadwood when
365 more large-sized wood was being shed from neighbouring trees. Meanwhile, we

366 found that termites disliked deadwood of high density, C:N ratio and lignin content
367 (Fig. 3 and Fig. S6). The amount and palatability of deadwood will therefore also
368 affect decomposition rates.

369 **4.2 Tree species richness increases the spatial variation of decomposition**

370 Multiple studies have documented significant effects of tree species identity on
371 decomposition rates (Vivanco and Austin, 2008; Gottschall et al., 2019; Peng et al.,
372 2022; Desie et al., 2023). Our study has aligned tree species identity effects at the
373 fine-scale with the spatial variation caused by tree species richness at the stand-level,
374 which is often overlooked when only focusing on the relationship between tree
375 species richness and the mean rate of wood decomposition (Eichenberg et al., 2017;
376 Joly et al., 2017; Pietsch et al., 2019). In accordance with our hypothesis, three of
377 seven tree species showed higher spatial variation of wood decomposition rates with
378 increasing tree species richness at the plot scale. This indicates that environmental
379 variation at the neighbourhood scale significantly alters decomposer activities and
380 thus wood decomposition rates. To more accurately predict fine-scale wood
381 decomposition rate in forests, the spatial variation in properties of neighbourhood
382 trees, e.g. canopy gap and shading (Griffiths et al., 2021), should be fully considered.

383 In addition to the shading effects of neighbourhood trees, plant functional traits
384 such as leaf tannin content and wood density could also impact decomposer activities
385 and wood decomposition rates. First, tannins are detrimental for microbes because
386 they inhibit extracellular enzymes, depriving the microbes of substrates for growth,
387 and directly affecting metabolism (Scalbert, 1991). As expected, we found that leaf
388 tannin content reduced fruitbody production, and even decreased termite activities,

389 probably by inactivating gut microbes and digestive enzymes (Ismayati et al., 2018).
390 Although fruitbody production was not positively related with wood decomposition
391 rates, tannins might influence fungal-mediated wood decomposition via unmeasured
392 pathways, such as decelerating enzyme activities and biomass accumulation
393 (Rubenstein et al., 2017). Second, wood density is one of the key traits that
394 mechanically hinders termites from efficient consumption (Liu et al., 2015; Cosme Jr
395 et al., 2018). Accordingly, we observed negative effects of deadwood density on
396 termite feeding intensity. Therefore, neighbourhood trees with higher mean wood
397 density could repel termites and thus indirectly lower wood decomposition rates (Fig.
398 3a, 3d) . Unexpectedly, mean leaf nitrogen content was unrelated with decomposer
399 activities or wood decomposition rates, even though deadwood C:N ratios negatively
400 affected termite activities and fruitbody production. Considering the high (> 50%) and
401 species-specific resorption rate of limiting nutrients (e.g. N) from senesced leaves,
402 nutrient traits of fresh leaves might not accurately represent those of litters (Vergutz et
403 al., 2012). Therefore, future studies should consider measuring nutrient traits of
404 senesced leaves to better predict decomposer activities and wood decomposition at the
405 neighbourhood scale.

406 **4.3 Tree species richness maintains decomposer activities over time**

407 In addition to the richness-decomposition relationship, our study also stresses the
408 critical role of tree species richness for maintaining wood decomposers and their
409 activities over the course of the decomposition process, as we found that
410 neighbourhood species richness increased termite occurrence, fruitbody number and
411 mycelium cover after two years. Note that although two years appear short to study

412 wood decomposition, branch samples in our study already reached ~72% mass loss
413 after two years. First, deadwood serves as the food resources and habitats for various
414 wood-dwelling organisms (Thorn et al., 2020), meaning that the size and biomass of
415 deadwood stocks are critical for preserving the longevity and diversity of saproxylic
416 communities not limited to decomposers (Sandström et al., 2019; Uhl et al., 2022).
417 We found that wood diameter was positively associated with termite activities at all
418 time-steps (Fig. 3) and fungal mycelium growth (i.e. the vegetative state) after one
419 year (Fig. S6b). Furthermore, fungal activities were negatively correlated with wood
420 decomposition rates (Table 2 and Fig. 4b). Given that fungi are one of the major wood
421 decomposer groups in forest ecosystems, it is unlikely that increasing fungal activities
422 would decrease wood decomposition rate. Instead, with termites being the dominant
423 decomposers, faster decomposition rates due to termite activity lower the remaining
424 wood biomass. This may reduce fungal activities through resource limitation. This
425 was further supported by the finding that neighbourhood tree volume positively
426 impacted fungal fruitbody number (Fig. 3f). These findings altogether indicate that
427 tree species richness could attract and strengthen decomposer activities through
428 increasing wood production (Kunz et al., 2019) and decreasing wood decomposition
429 rates. Second, diversifying decomposition rates could contribute to the spatial and
430 temporal ‘source-sink’ dynamics of decomposer communities among deadwood of
431 different decay stages (Benbow et al., 2019). Comparatively speaking, termites are
432 early colonists (Ulyshen, 2016), whereas fungal diversity often peaks in advanced
433 stages of decomposition (Kubartová et al., 2015). As expected, we observed that
434 termite feeding marks were common for samples after one year of decomposition

435 (Fig. S7), whereas fungal marks were scarce until the second year (Fig. S8).
436 Considering that saproxylic taxa colonize and utilize deadwood at different decay
437 stages (Stokland and Siitonen, 2012; Yang et al., 2021), increasing the spatial
438 variation of wood decomposition rates by increasing tree species richness could
439 contribute to the conservation of saproxylic species diversity.

440 Finally, increasing tree species richness could enhance environmental
441 heterogeneity, and thus mitigate interspecific competition among decomposers via
442 niche partitioning. Consistent with previous studies (Ulyshen et al., 2016; Bradford et
443 al., 2021), we found that termite feeding suppressed fungal activities, especially
444 fruitbody production. This pattern could be due to the resource limitation caused by
445 termite feeding and also due to the anti-fungal substances released by termites
446 (Bulmer et al., 2012; Martin and Bulmer, 2018). We observed that fungi performed
447 better in the absence of termites. First, fungal activities tended to increase with
448 deadwood density and neighbourhood mean wood density. The only exception was
449 that fruitbody production after two years of decomposition was higher for lower
450 density deadwood. Given that the economic spectrum of wood traits shows a hump-
451 shaped relationship with termite foraging populations in deadwood at later stages of
452 decay (Guo et al., 2021), the predictive power of initial wood traits on decomposer
453 activities weakens as decomposition proceeds. Fungal fruiting processes might be
454 sensitive to such changes. Second, termites and fungi seemed to prefer different
455 temperatures, which is consistent with empirical studies (Jonsson and Stokland, 2012;
456 Zanne et al., 2022). We found that air temperature increased termite activities whilst
457 suppressing fungal mycelium cover, and neighbourhood tree volume suppressed

458 termite occurrence whilst enhancing fungal fruitbody production. Altogether, these
459 findings suggest that fungi could avoid intense competition by occupying undesired
460 niches of termites.

461 **4.4 Conclusions**

462 Using a neighbourhood approach, we found evidence for the positive effects of
463 tree species richness on the patchiness but not the overall mean of wood
464 decomposition. Diverse stands in young forests or those undergoing regeneration will
465 experience cooler understory and thus lower rates of decomposition, due to the faster
466 volume growth and the suppression of termite feeding activity. Furthermore, different
467 tree species composition and functional traits at the neighbourhood scale strengthens
468 environmental heterogeneity and thus the spatial variation of decomposer activities
469 and wood decomposition rates. Altogether, our findings suggest that: 1) young
470 regenerating species-rich forests could maintain higher deadwood stocks by
471 decreasing wood decomposition rates, where termites are dominant decomposers; 2)
472 decomposition will be patchier in species-rich forests, which can be predicted by
473 crown shading and plant functional traits at the neighbourhood scale. Meanwhile, our
474 study suggests that tree species richness could contribute to the persistence of
475 decomposers by weakening resource limitation, and increasing the heterogeneity of
476 stages of wood decay. While two years seem to be enough for branch samples to be
477 highly decomposed in our study, future studies might consider monitoring
478 decomposer communities for longer temporal span (e.g. 3-5 years for coarse woody
479 debris) to verify if tree species richness drives the long-term maintenance of
480 decomposer activities.

481 Two open questions remain unresolved in our study. First, some species showed
482 significant responses to tree species richness while others did not. While the small
483 sample size ($n = 3$) per species per plot might not be enough to detect patterns, wood
484 traits and quality might also alter the species richness effect. For example, species
485 with higher lignin content would suffer from stronger negative effects by
486 neighbourhood tree species richness (Table S8; marginally significant interaction
487 between lignin content and richness). Future studies could select more species of
488 varying traits to better understand the interaction effects between wood traits and
489 neighbourhood species richness. Second, neighbourhood effects of tree communities
490 might change with topography, for instance, the variation associated with sloping
491 terrain. We found that terrain slope strengthened the effects of five neighbourhood
492 metrics on fungal fruitbody number but not wood mass loss and the other proxies of
493 decomposer activities (Table S9-S13). More studies would be needed to resolve the
494 intricate effects of neighbourhood trees on decomposition given the complex terrain
495 in many forest ecosystems.

769

770 **Fig. 1** Plot tree species richness effects on wood mass loss of seven species. The
771 response variable of the left and right panel is the mean rate and the spatial variation
772 of wood mass loss, respectively. The upper (or lower) panels refer to 1-year (or 2-
773 year) decomposition. Significant ($p \leq 0.05$) relationships are printed as solid lines
774 with the 95% confidence interval; marginally significant ($0.05 < p < 0.1$) relationships
775 are printed as solid lines; insignificant ($p \geq 0.1$) relationships are printed as dashed
776 lines.

777 **Fig. 2** Neighbourhood tree species richness effects on sample-level wood mass loss of
778 seven species. The predictor variable of the left and right panel includes and excludes
779 zero values, respectively. The upper (or lower) panels refer to 1-year (or 2-year)
780 decomposition. Significant ($p \leq 0.05$) relationships are printed as solid lines with 95%
781 confidence intervals; marginally significant ($0.05 < p < 0.1$) relationships are printed
782 as solid lines; insignificant ($p \geq 0.1$) relationships are printed as dashed lines.

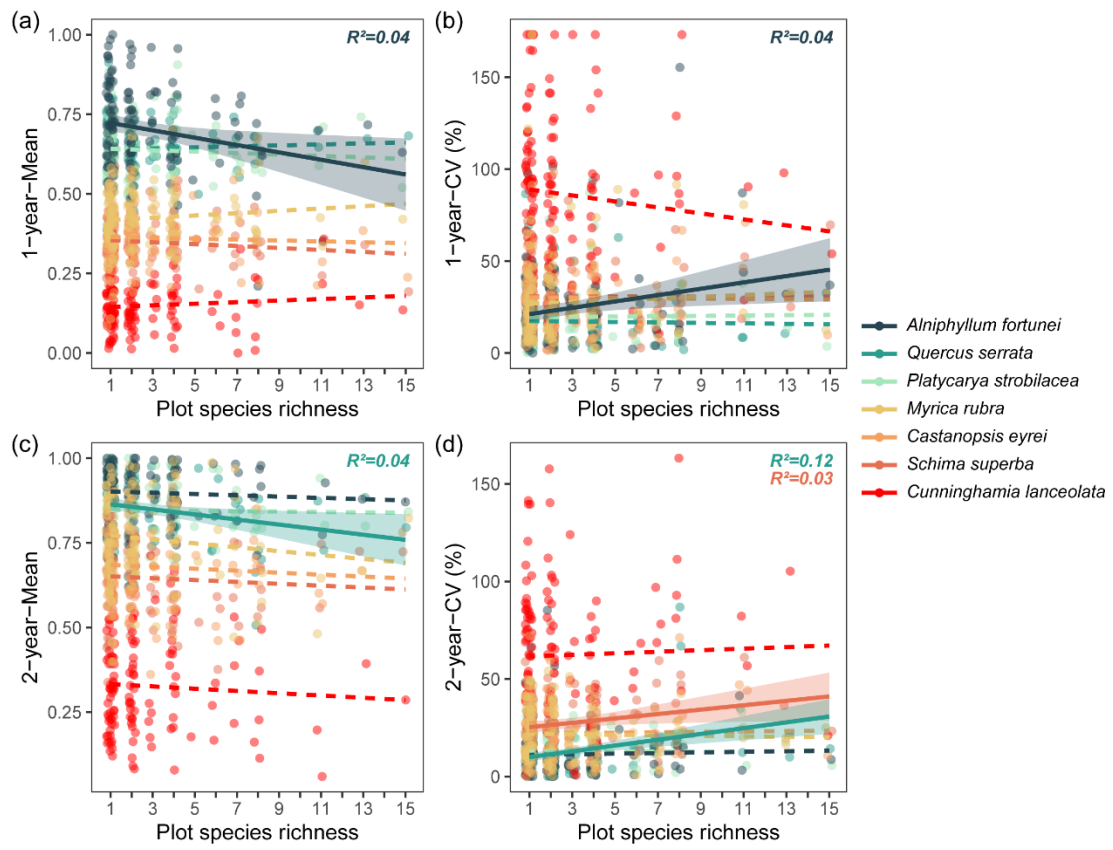

783 **Fig. 3** Bivariate generalised linear mixed model results of wood mass loss and
784 decomposer activities. The response variable of the left, middle and right panels is
785 wood mass loss, termite occurrence and fruitbody number, respectively. The upper (or
786 lower) panels refer to 1-year (or 2-year) decomposition. The mean (dot) and 95%
787 confidence intervals (bars) of the standardised parameter estimates for each of five
788 wood traits and five neighbourhood metrics were reported separately. Note that
789 positive effects are printed in black while negative effects in red. Significance is
790 indicated as: +, $0.05 < p < 0.1$; *, $p \leq 0.05$; **, $p \leq 0.01$; ***, $p \leq 0.001$.

791 **Fig. 4** The piecewise structural equation model results after 1-year (a) and 2-year
792 decomposition (b). The causal relationship is denoted as the single-arrow line while

793 the correlative relationship as the double-arrow line. Wood traits (in the brown box)
794 and neighbourhood metrics (in the green box) are distinguished by colour. The path
795 coefficients and model fits (in the grey box) are reported, as well as the marginal (and
796 conditional) R^2 . Note that all significant paths are solid lines ($p \leq 0.05$) except for the
797 dashed paths ($0.05 < p < 0.1$). Path colour indicates the direction of relationship, with
798 positive in black and negative in red. The paths related to neighbourhood tree species
799 richness are printed thicker for readers' convenience.

800 **Fig. 5** The linear relationship among tree species richness, total tree volume and mean
801 air temperature. The upper panel tests the linear relationship at the plot scale while the
802 lower panel at the neighbourhood scale. Total tree volume is $\log(1+V)$ transformed
803 before analysis. Note that plot species richness effect on plot tree volume is
804 marginally significant ($0.05 < p < 0.1$) while the other linear relationships are
805 significant ($p \leq 0.05$). The piecewise structural equation models are used to
806 summarise the relationship between three variables at the plot scale (c) and at the
807 neighbourhood scale (f).
