ABSTRACT

Dark spot disease (DSD) was first reported within Florida's coral reefs in the 1990s but factors affecting its spatial distribution have not been well studied. We used a 14-year (2005-2019) coral monitoring data set, utilizing 2,242 surveys collected along Florida's coral reefs (~530 linear km) to explore the spatial and temporal patterns of DSD occurrence. We built predictive statistical models to test for correlations between a suite of environmental and human impact factors and the occurrence of DSD in the reef coral, *Siderastrea siderea*. DSD in *S. siderea* is a chronic disease which occurred in all 14 years of the study. Annual DSD prevalence ranged from 0.45% to 4.4% and the proportion of survey sites that had DSD ranged from 4.8% to 30.9%. During the study period, DSD became more widespread across Florida's coral reefs and affected a higher proportion of *S. siderea* populations. Spatial variations in DSD correlated with environmental and human factors which together explained 64.4% of the underlying variability. The most influential factors were concentration of silica in the surface waters (a proxy for freshwater input), the total number of coral hosts, and distance to septic areas. DSD occurred in all regions, but the highest cumulative prevalence occurred in the upper Keys on reefs around major urban centers with links to coastal water discharges. Our results support the hypothesis that coastal water quality is a key component of DSD disease dynamics in Florida and provides motivation for addressing land-sea connections to ameliorate disease occurrence in the region.

INTRODUCTION

Disease is a normal component of host populations, but increased levels of disease can indicate changes in host-pathogen ecology often due to shifting environmental conditions (Schrag and Wiener 1995, Daszak et al. 2000). Climate change and environmental degradation from local human impacts are cited as major influences contributing to disease outbreaks in wildlife populations (Daszak et al. 2000, Dobson and Foufopoulos 2001, Lafferty and Holt 2003) including reef corals (Harvell et al. 1999, 2007, Carpenter et al. 2008, Maynard et al. 2015). Diseases in corals have become a problem worldwide with outbreaks reported from the Indo-Pacific (Willis et al. 2004, Myers and Raymundo 2009, Aeby et al. 2011a, 2015, 2016, Haapkylä et al. 2011), Persian Gulf (Howells et al. 2020, Aeby et al. 2020), Indian Ocean (Thinesh et al. 2009, Raj et al. 2016) and western Atlantic (Patterson et al. 2002, Miller et al. 2009, Voss and Richardson 2006, Croquer and Weil 2009, Brandt et al. 2012, Croquer et al. 2021). The most devastating coral disease in recent history, stony coral tissue loss disease, emerged in Florida in 2014 (Precht et al. 2016) and continues to spread across the Caribbean, causing significant mortality on affected coral reefs (Walton et al. 2018, Alvarez-Filip et al. 2019, Sharp et al. 2020, Heres et al. 2021, Estrada-Saldivar et al. 2021). Coral disease is a major threat to the survival of coral reefs and identifying the primary factors affecting coral disease dynamics is key to designing effective local mitigation strategies, prioritizing disease intervention resources, and identifying areas suitable for reef restoration.

Environmental factors can affect host-pathogen dynamics by impairing host immune responses and enhancing pathogen abundance, transmission, or virulence (Daszak et al. 2001, Dobson and Foufopoulos 2001, Harvell et al. 2007) and several environmental conditions have emerged as important in driving increased disease levels in corals. Thermal stress has been linked to numerous disease outbreaks (Bruno et al. 2007, Miller et al. 2009, Bruno 2015,

70 Brodnicke et al. 2019, Howells et al. 2020) with higher ocean temperatures thought to impair
71 coral immune responses as well as enhance pathogen abundance and virulence (Mydlarz et al.
72 2009, Maynard et al. 2015, Ushijima et al. 2016, Vega Thurber et al. 2020). Lamb et al. (2018)
73 found that disease establishment was facilitated via abrasion of corals by plastics, allowing
74 pathogen invasion, reducing coral resources for immune function due to wound healing and by
75 the colonization of plastics by pathogens. Poor water quality due to dredging (Pollock et al.
76 2014), land-based runoff (Haapkylä et al. 2011, Sheridan et al. 2014, Aeby et al. 2016) and
77 eutrophication (Bruno et al. 2003, Vega Thurber et al. 2014) have also been implicated in
78 increasing disease prevalence. A common component of all these studies is the link between
79 increases in coral disease and changes in environmental conditions due to anthropogenic actions.
80 Dark spot disease (DSD), also called dark spot syndrome (DSS), is a disease reported on
81 coral reefs across the wider Caribbean (23 countries) affecting 16 coral species (Work and Weil
82 2016). DSD manifests as multi-focal or coalescing spots of dark discolored tissue (Fig. 1) that
83 can spread across the coral surface causing slow, progressive tissue loss (Work and Weil 2016).
84 DSD lesions can also resolve and appear elsewhere on the colony (Borger et al. 2005, Gochfeld
85 et al. 2006, Porter et al. 2011) and it is unclear what determines the trajectory of these lesions.
86 Corals with similar disease signs from the Indo-Pacific (Work et al. 2008, 2014), and Red Sea
87 (Aeby et al. 2021) are termed 'endolithic hypermycosis' as histopathology showed the lesions to
88 be associated with endolithic fungal infections (Work et al. 2008, 2014, Aeby et al. 2021). In the
89 Caribbean, the etiology of DSD is less certain, although Renegar et al. (2008) also found
90 endolithic fungal infections in DSD-affected *Siderastrea siderea.* Cervino et al. (2001) showed
91 that zooxanthellae from dark spot lesions are swollen and darker in pigment and suggested DSD
92 was primarily a disease of the symbiotic zooxanthellae found within the coral host. The lesions

identified as DSD may have multiple underlying etiologies, as proposed for tissue loss diseases (white syndromes) (Bourne et al. 2014) or may instead be a general stress response, as suggested by Borger et al. (2005). Although DSD affects multiple coral species on coral reefs across the Caribbean, it is not well studied (Work and Weil 2016).

Dark spot disease (DSD) has been affecting Florida's corals since the 1990s (Santavy et al. 2001) but little is known about the ecology of DSD in this region. We used a 14-year (2005-2019) coral disease monitoring data set, collected along Florida's extensive Coral Reefs Tract (~530 linear km), to explore DSD occurrence along a gradient of human and environmental factors. Specifically, we examined the spatial and temporal patterns of DSD prevalence (percent of corals affected) and frequency of occurrence among survey sites in the common coral host, *Siderastrea siderea,* and used statistical modeling to explore some of the underlying co-factors that correlate with DSD occurrence. This is the first regional-scale investigation of DSD patterns along the Florida Reef Tract.

METHODS

Study area

The Florida Reef Tract is a predominantly continental reef system which spans approximately 595 linear km of coastline from the Dry Tortugas National Park in the southwest to Martin County in the northeast (Walker et al. 2013). It is a large barrier reef ecosystem composed of over 45 species of stony corals, and is a critical ecosystem that provides coastal protection, supports a large tourism industry, and hosts a wide variety of commercially and ecologically important marine species.

Disease surveys

We used data collected as part of the Florida Reef Resilience Program's (FRRP) Disturbance Response Monitoring program (DRM)(https://frrp.org/coral-monitoring/). The DRM uses a stratified random sample design across 28 discrete reef zones in 10 sub-regions. At each site, two independent 1x10 m belt transects were surveyed with all coral colonies with maximum diameter >4 cm identified to species, enumerated and their health condition noted. The data are available from Florida Fish and Wildlife Conservation Commission (https://ocean.floridamarine.org/FRRP/). For our analysis, we used a subset of the data, limiting it to the coral species, *Siderastrea siderea*, and the health condition noted as dark spot disease (DSD). *Siderastrea siderea* is a widespread species occurring across the Caribbean and is the most common host of DSD (Gil-Agudelo et al. 2001, Weil 2004, Borger 2005, Gochfeld et al. 2006, Voss and Richardson 2006). The dataset used in our analyses included 2,442 individual surveys from 2005-2019, excluding 2017 due to low and inconsistent sampling effort that year after hurricane Irma (Fig. 2). From these data, we calculated DSD prevalence, defined as the percent of colonies surveyed at each site that had a lesion consistent with DSD. Overall prevalence was the proportion of all colonies that had a DSD lesion (all surveys combined). Frequency of disease occurrence (FOC) is a measure of spatial distribution of disease and was calculated as the percentage of survey sites having one or more coral colonies manifesting DSD. There was a large increase in DSD prevalence and FOC between the time periods 2005-2012 and 2013-2019. Thus, differences in DSD prevalence and FOC between these two time periods were analyzed using a non-parametric Wilcoxon 2-group test (JMP vers. 16.1). Regional patterns of DSD prevalence were explored with the data split by ecoregions (Walker 2012). Differences in DSD prevalence among ecoregions was examined by calculating the cumulative average DSD prevalence for surveys between 2005 and 2019 (excluding 2017).

Modeling the association between DSD and multiple human and environmental factors

Several predictor variables were hypothesized to be linked to spatial variations in coral disease dynamics, including 1) The Nature Conservancy's (TNC) Ocean Wealth Index (as a proxy of reef "use" by people), 2) impacts from wastewater, 3) septic tanks (potential sewage pollution), 4) local land use (as indicators of local coastal development), 5) water quality, and 6) local human populations. These were quantified using multiple data sources and across a range of scales and combined with measurements of survey depth, susceptible coral host abundance (i.e., the abundance of *Siderastrea siderea* at each site), survey year (to account for the temporally variable nature of the disease data), and a range of metrics that captured variations in reef habitat (Table 1). For our predictor groups 1– 6 above, we quantified each of them within a radial distance of each survey location over a range of spatial scales using a Fibonacci sequence (1, 2, 3, 5, 8, 13 and 21 km). We examined different spatial scales for predictor variables as the influence each predictor might have on our disease response variable could vary depending on their distance from the survey locations. In some cases, there was a high proportion of missing data values over the smaller scales for some predictor variables (e.g., 1 – 8km for water quality estimates and wastewater treatment facilities) so these scales were excluded prior to model fitting (see Table 1 for the final scales included for each predictor). Despite our knowledge that some of the predictor variables were likely collinear, given the large replication in the response variable, and the fact that our chosen modeling framework (see below) is robust to the inclusion of spurious predictors, we included all predictors in the model fitting process.

Statistical models were built using a boosted regression tree (BRT) framework to test the ability of the predictor variables to explain variation in the number of diseased coral hosts across

the Florida Reef Tract. Unlike many modeling techniques that aim to fit a single parsimonious model, BRT incorporates machine learning decision tree methods (Breiman et al. 1984) and boosting, a method to reduce predictive error (Elith et al. 2008), to build an additive regression model in which individual terms are regression trees, fitted in a forward stage-wise manner (i.e., sequentially fitting each new tree to the residuals from the previous ones). In summary, BRT gives two crucial pieces of information, namely the underlying relationship between the response and each predictor, and the strongest statistical predictor (among the simultaneously tested predictors) of the response variable in question. Due to their flexible use and improved predictive power, the use of BRTs has increased over recent years to model non-linear ecological relationships at a range of spatial scales including coral reef-environment associations (e.g., Williams et al. 2010, Gove et al. 2015, Aston et al. 2019).

BRTs were constructed using the *gbm.step* routine (Elith et al. 2008) in the *dismo* package (Hijmans et al. 2017) for R (www.r-project.org) and all model outputs were visualized in *ggplot2* using *ggBRT* (Jouffray et al. 2019). The data were modeled using a Poisson distribution, as our response variable was the number of corals in each survey location showing signs of DSD (i.e., number of disease cases). Number of disease cases was used rather than disease prevalence (# cases/total # colonies surveyed) as host abundance was already included in the model. We used a 10-fold cross-validation approach to test the model against withheld portions of the data (iterated thousands of times) and the cross-validated percentage deviance explained, calculated as (1 – (cross-validated deviance/mean total deviance)), as our measure of model performance (Jouffray et al. 2019). To optimize model predictive performance, we varied three core parameters of the BRT algorithm: the *bag-fraction* (bf, proportion of data to be selected at each step), the *learning rate* (lr, used to shrink the contribution of each tree as it is added to the

185 model), and the *tree complexity* (tc the number of terminal nodes in a tree). Using a customized
186 loop routine (Richards et al. 2012), we identified the combination of these three parameters that
187 resulted in the lowest cross-validation deviance (CVD) over bf-values 0.5, 0.7, and 0.8, lr-values
188 0.001, 0.0001, and 0.00001, and tc-values 1–5, while maintaining a minimum of ≥ 1000 fitted
189 trees and a maximum of 50,000 trees. This identified the following optimal model parameter
190 settings: bf = 0.8, lr = 0.001, tc = 2. We calculated the relative importance of each predictor
191 based on the number of times a variable was selected for splitting, weighted by the squared
192 improvement to the model as a result of each split, and averaged over all trees (Friedman and
193 Meulman 2003, Elith et al. 2008). To assess the relative contribution of each predictor, we only
194 considered predictors with a relative influence above that expected by chance (100/number of
195 variables) (Muller et al. 2013) and then rescaled their influence to 100%. The interactive effect
196 of the most influential predictors was then visualized using the *ggInteract_3D* function within
197 *ggBRT*. All input data (DSD.csv) and R code (DSD_Cases_BRT_Florida.R) used to execute our
198 BRT models are provided as Supplementary Materials.
199
200 **RESULTS**
201 ***DSD prevalence through time within S. siderea populations across the Florida Reef Tract***
202 Between 2005 and 2019, mean (±1SE) DSD prevalence among all sites and all years was
203 2% (± 0.4%). DSD was observed in every year of the survey period (14 years) and mean DSD
204 prevalence ranged from a low of 0.45% in 2006 to a high of 4.4% in 2016. Overall, DSD
205 prevalence (all sites combined) increased through time, with mean DSD prevalence before 2013
206 (2005-2012) equaling 1.1% (±0.17%) compared to 2.9% (±0.27%) from 2013-2019 (Fig. 3)
207 (Wilcoxon 2-group test, Z=2.9, p=0.0037).

Distribution of DSD through time across the Florida Reef Tract

Region-wide distribution of DSD within our study period was 14.6% with 357 of the 2,442 survey sites having colonies with DSD signs (all years combined). Frequency of occurrence ranged from a low of 4.8% (n=84 sites) in 2005 to a high of 30.9% (n=188 sites) in 2018 (Fig. 4). Through time, DSD occurrence increased from 7.4% ($\pm$0.8%) of survey sites between 2005 and 2012 to an average of 22.1% ($\pm$2.8%) of survey sites between 2013-2019 (Wilcoxon 2-group test, Z=2.9, p=0.0037).

Association between DSD and suspected human and environmental drivers

Our predictive model explained 64.4% of the underlying spatial deviance in the number of DSD cases across the entire dataset (Table 2). The top three predictors contributed 45.5% of the relative influence within the model and included the concentration of silica in the surface waters within a 13 km radius (proxy for freshwater input), the total number of susceptible coral hosts (*S. siderea*), and the number of septic areas within an 8 km radius. When predicting to new data from the training data, 47.1% of the cross-validated percentage deviance was explained, suggesting a reasonable ability to predict to new data. The probability of DSD occurrence increased as both surface water silica concentration and coral host abundances increased and became maximized where silica exceeded 1.15 µM/L and where there were >100 coral hosts within the survey area (Fig. 5A). DSD occurrence was also higher in areas with >13 km^2 septic areas within 8 km regardless of coral host abundance but was highest where there were also >100 coral hosts (Fig. 5B).

Other significant variables in the model were year of the study (consistent with our findings of increased DSD levels through time), survey depth, habitat characterization (URM ClassLv4, Reef Zone)(https://myfwc.com/research/gis/regional-projects/unified-reef-map/), measures of water quality, total carbon in surface waters within 8 km and in bottom waters within 21 km, and total phosphorous in bottom waters within 21 km, and surface waters within 8 km, distance to pollution sources (number of sewer systems within 21 km and number of septic systems within 8 km) and variables associated with human impacts (amount of spending within 1 and 5 km which indicates degree of human presence and degree of urbanization within 8 km which could influence coastal runoff and pollution).

Regional distribution of DSD and the association with predictor variables across the Florida Reef Tract

S. siderea colonies with DSD were found throughout the Florida Reef Tract but there was a distinct spatial clustering of DSD colonies on reefs around the upper Keys (Fig. 6) where there was a threshold concentration of silica in the water and a threshold area of septic systems within 8 km of the survey sites (Fig. 7).

DISCUSSION

In the first long-term study examining dark spot disease (DSD) occurrence across the Florida Reef Tract, DSD in *Siderastrea siderea* was found to be a chronic disease occurring in the annual monitoring surveys in all 14 years of the study. Between 2005 and 2019, *S. siderea* DSD prevalence ranged from less than 0.5% to over 4% which is less than from prior studies in Florida and regions in the Caribbean. In Florida, DSD prevalence in *S. siderea* was found to be

253 between 4.3% to 13.3% (Porter et al. 2011), and in the Caribbean reported studies found 25% in
254 Columbia (Gil-Agudelo & Garzon-Ferreira 2001), 53% in Bonaire, 58% in Turks and Caicos,
255 and 42% in Grenada (Cervino et al. 2001). We only found an average DSD prevalence of 2%
256 (all years combined) but the spatial and temporal coverage from the number of surveys we
257 examined (2508 surveys across 15 years) far exceeded the spatial and temporal scale of other
258 studies which might explain these differences. Indeed, we did find higher DSD prevalence at
259 smaller spatial and temporal scales. As example, in the upper Florida Keys, DSD prevalence
260 was 19.4% in 2014 and 22% in 2016. In addition, human and environmental variables are also
261 important factors underlying disease occurrence which also vary in time and space.
262 DSD became more widespread across Florida's coral reefs and affected a higher
263 proportion of *S. siderea* populations through time. DSD was found in 7% of the total surveys
264 between 2005 and 2012 but occurred in 22% of the surveys between 2013 and 2019. Similarly,
265 average DSD prevalence was approximately 1% of the surveyed corals from 2005 to 2012 but
266 affected nearly 3% of *S. siderea* colonies thereafter. As with most coral diseases, pinpointing a
267 cause to this increase in DSD occurrence through time is challenging. We ruled out changes in
268 methods or field personnel and there were no obvious acute environmental events (bleaching,
269 hurricanes, annual rainfall) that could explain changing disease levels. Previous studies have
270 shown that DSD is dynamic, with colonies recovering and becoming reinfected over time
271 (Gochfeld et al. 2006, Porter et al. 2011). However, our data indicate a persistent and increasing
272 annual DSD prevalence from 2012 – 2019, indicative of a chronic source or stressor. Florida's
273 coral reefs have been increasingly impacted by humans with densely populated coastlines, higher
274 visitor numbers, and chronic polluted terrestrial run-off for many decades (Jackson et al. 2014).
275 Florida has also suffered an acceleration of both acute and chronic thermal stress over the past 30

276 years with reefs experiencing six mass bleaching events since the late 1980s (Manzello 2015)
277 with the most recent event occurring in 2014 (Eakin et al. 2019, van Woesik and McCaffrey
278 2017). It is plausible that Florida's coral reefs have reached the limit of their ability to tolerate
279 multiple, possibly additive or synergistic stressors which may be affecting the coral's ability to
280 resist disease.

281 Statistical modeling found host density, indicators of freshwater input, and proximity to
282 septic systems were the strongest predictors of DSD, suggesting that environmental and
283 anthropogenic stress are important drivers of this disease across the Florida Reef Tract. It must
284 be noted that other factors may be important in determining DSD levels in regions where
285 pollution is less problematic. Identifying the cause of DSD will help in teasing out all relevant
286 environmental co-factors. However, for Florida's reefs polluted waters have been identified as a
287 major problem for decades (Zhao et al. 2013). Florida's long history of coastal pollution has
288 resulted in harmful algal blooms, seagrass die-offs, and declining coral reefs, with wastewater
289 and on-site sewage treatment and disposal systems (OSTDS) representing major nitrogen sources
290 contributing to ecosystem impacts (Lapointe et al. 2004, 2015). In addition to excess nitrogen,
291 sewage pollution also results in coastal influxes of freshwater, phosphorous, pathogens,
292 endocrine disrupters, suspended solids, sediments, heavy metals, and other toxicants (Wear and
293 Vega Thurber 2015). Evidence of sewage pollution is common in Florida's nearshore
294 environments with human fecal contamination of nearshore or offshore coral reefs found along
295 the Florida Reef Tract (Lipp et al. 2002, Futch et al. 2010, 2011, Staley et al. 2017). Sewage can
296 also act as a reservoir for potential pathogens as evidenced by Sutherland et al. (2011) who found
297 human wastewater to be a source of the pathogen causing white pox disease in the reef coral,
298 *Acropora palmata*. Additionally, freshwater stress alone can increase a coral's susceptibility to

bacterial infections (Shore-Maggio et al. 2018) and numerous field studies show a link between rainfall, terrestrial run-off, and disease outbreaks (Haapkylä et al. 2011, Sheridan et al. 2014, Aeby et al. 2016).

It is not usually a single stressor that results in the emergence of disease but multiple co-factors. Coastal runoff exposes nearshore coral reefs to sediments, freshwater, excess nutrients, and other pollutants. Other studies support the importance of multiple stressors impacting coral reefs. Oberle et al. (2019) found a combination of nutrient loading and low salinities from groundwater discharge explained an outbreak of black band disease on coral reefs in Hawaii. Considering the long-term problems Florida has had with polluted waters, it is not surprising that we found a link between DSD levels, proximity to sewage sources and indicators of land-based freshwater influx. Similarly, Porter et al. (2001) showed a five-fold increase in number of survey stations with disease over time in the Florida Keys and this trend was especially evident on reefs close to the population centers of Key West and Key Largo. In additional support of our findings, Vega Thurber et al. (2014) showed a direct link between excess nitrogen and DSD development in *S. siderea.* In an *in situ* nutrient enrichment experiment, they found *S. siderea* in treatment plots, had a 100% increase in DSD compared to corals in control plots.

Spatial analyses among regions showed that the progressively higher DSD prevalence through time, was especially prominent in the upper Florida Keys. The upper Florida Keys were also associated with higher levels of silica indicating an influx of freshwater, and larger septic areas, two of the top predictor variables explaining DSD occurrence along the Florida Reef Tract. Several changes in local water management have occurred around the upper Keys since 2012 that might have influenced the amount of freshwater, and thus levels of DSD, occurring in that region, namely the development of wastewater management systems, and changes in the

management of the Everglades canal system. Wastewater is recognized as a historic source of excess nutrients into local Florida waters (Barreras et al. 2019) and billions of dollars have been spent developing wastewater management systems to convert septic systems to sewer. In the upper Keys, there are two water management districts, Key Largo Wastewater Treatment District (KLWTD) and the North Key Largo Utility Corporation (Barreras et al 2019). The KLWTD advanced wastewater treatment system was completed in 2010 and effluent from this system is deep-well injected to reduce pollution in nearshore marine waters (Reich et al. 2002, Chanton et al. 2003). Implementation of these systems has shown improvements in water local quality (Barreras et al. 2019, Kelly et al. 2021) so wastewater seems a less likely cause of increased disease within this region. However, deep-well injected wastewater on the island of Maui in Hawaii was found to be a significant source of eutrophication on adjacent coral reefs, contributing to their decline (Dailer et al. 2010, Murray et al. 2019).

Conversely, freshwater from the heavily managed and controlled Everglades canal system has been shown to affect much of the Florida Keys coral reef system (Lapointe et al 2019). This water contains runoff from both urban and agriculture areas that can result in 'black water' events where patches of dark colored water develop due to high concentrations of phytoplankton and colored dissolved organic matter (Hu 2004, Zhao et al. 2013). Lapointe et al. (2019) implicate this water as the main source of enriched nutrients to the reef system and a primary driver of coral reef decline in the lower Florida Keys over the past few decades. Given that increasing the freshwater flows from the Everglades has been a priority for managers for decades (NOAA 1996), it is also possible that these flows are increasing DSD. Clearly, more research is needed to understand the source and dynamics of DSD in the Florida Keys.

Host density was also a significant factor in explaining DSD occurrence across the Florida Reef Tract. A positive relationship between host abundance and disease has been demonstrated for numerous host-pathogen systems (Altizer and Augustine 1997, McCallum et al. 2004, Lafferty 2004) including DSD (Borger and Steiner 2005) and other coral diseases (Bruno et al. 2007, Haapkylä et al. 2009, Aeby et al. 2010). High host density can result in increased transmission of disease throughout a population as distance between individuals decreases. However, this would only apply toward infectious diseases, and it is not known whether DSD is infectious. DSD is not well studied, but to date, there is no evidence that DSD is infectious (Randall et al. 2016). However, if DSD were an environmentally induced disease, then host density could still play a role in predicting disease occurrence (e.g., more corals exposed to the adverse environmental conditions would lead to higher local disease levels).

On the Florida Reef Tract, *S. siderea* densities have been increasing through time (Hayes et al. 2022), and it is thought that weedy species, such as *S. siderea*, are becoming more common due to the declines of historically dominant species (Burman et al. 2012, Jones et al. 2020). The species that have declined the most were also the most stenotopic species, i.e., those able to tolerate a narrower range of environmental conditions (Burman et al. 2012). Increasing thermal stress events combined with multiple disease outbreaks have led to this shift in coral community structure (Burman et al. 2012, Jones et al. 2020). Understanding disease in *S. siderea* is becoming even more important as its numerical dominance increases throughout the Florida Reef Tract.

Several studies have suggested DSD is caused by the overgrowth of endolithic fungi (Work et al. 2008, 2014, Renegar et al. 2008) and it is plausible that DSD is an environmentally induced disease whereby environmental stressors are disrupting the coral holobiont facilitating

fungal overgrowth. If so, the environmental stressors and thus underlying drivers of DSD may also differ between regions explaining why pollution may be important in driving DSD on Florida's reefs but perhaps not in other regions. Corals live in a dynamic partnership between the cnidarian host, its endosymbiotic dinoflagellates, and a suite of microbiota that includes archaea, bacteria, viruses, fungi, and endolithic algae (Rosenberg et al. 2007, Bourne et al. 2009, Boilard et al. 2020). Environmental conditions that disrupt the delicate balance among partners create imbalances or dysbiosis which can result in disease (Lesser et al. 2007, Bourne et al. 2009, Vega Thurber et al. 2020). MacKnight et al. (2021) examined the link between microbial dysbiosis and disease susceptibility of seven Caribbean coral species exposed to white plague disease. They found that coral species that showed comparatively higher microbial dysbiosis had the greatest susceptibility to infection upon exposure to white plague. Diseases in marine organisms are more often due to dysbiosis and the emergence of opportunistic pathogens rather than infection by a single pathogen (Lesser et al. 2007, Burge 2014, Egan et al. 2014. Egan and Gardner 2016). In other cases, pathogens can live as a component of a host's normal microbiome but under certain conditions switch from a commensal to a pathogen. For example, the marine bacterium *Phaeobacter gallaeciensis* BS107 is a commensal on the microalgae, *Emiliania huxleyi*, and produces compounds that are beneficial to its algal host (Seyedsayamdost et al. 2011). However, in response to p-coumaric acid, a breakdown product symptomatic of aging algae, *Phaeobacter gallaeciensis* BS107 initiates production of potent algaecides becoming an opportunistic pathogen of its algal host. Whether or not DSD is caused by a disruption of the symbiosis between the coral host and its fungal endoliths will require further research on the ecology and etiology of this disease.

389 Interestingly, human population densities were not significant in explaining DSD
390 occurrence unlike studies of other coral diseases (e.g., growth anomalies: Aeby et al. 2011b)
391 where human populations were associated with disease. Instead, the amount of spending was an
392 important factor reflecting Florida's resident population as well as its extensive visitor numbers.
393 Florida's resident population is around 22 million (https://www.populationu.com/us/florida-
394 population) whereas it hosted 122 million visitors in 2021
395 (https://www.visitflorida.org/resources/research/). For Florida, this metric (spending) appears to
396 be a better indicator of potential degree of human impacts rather than simply resident human
397 population. Other important variables identified in the model (measures of water quality,
398 distance to pollution sources, degree of urbanization that influence coastal runoff and pollution)
399 confirm anthropogenic impacts as a major influence on coral disease occurrence.
400 Florida's coral reefs have declined over the past several decades with increased coastal
401 populations, high visitor numbers, overfishing, and impaired water quality contributing to their
402 decline. Florida is also considered a "coral disease hotspot" with disease outbreaks occurring
403 repeatedly since the 1970s (Dustan 1977, Richardson 1998, Green and Bruckner 2000, Precht et
404 al. 2016, van Woesik and McCaffrey 2017). The downward trend of Florida's coral reefs
405 continues with a recent study on southeast Florida coral populations by Walton et al. (2018) who
406 found region-wide declines in coral diversity, density and live tissue area which was attributed to
407 disease. Our study documents the long-term persistence of disease in *S. siderea*, a common reef
408 coral across Florida, and our modeling results suggest that coastal water quality is a key
409 component to coral reef disease management, including maximizing resiliency in the face of
410 global climate change. Disease not only impact host populations but can also result in
411 ecosystem-wide impacts due to mortality of keystone species (Burge et al. 2014). Diseases are

412 predicted to increase with global climate change and anthropogenic pressures (Gattuso et al.
413 2015, Maynard et al. 2015), placing more emphasis on the need to further understand drivers of
414 marine diseases.
415
416 **ACKNOWLEDGEMENTS**
417 We thank the Florida Department of Environmental Protection's Office of Resilience and
418 Coastal Protection and to NOAA's National Centers for Coastal Ocean Science for supporting
419 these efforts. Thank you to J Stein and the Florida Fish and Wildlife Conservation Commission
420 Fish and Wildlife Research Institute's Florida Reef Resilience Program Disturbance Response
421 Monitoring for facilitating data requests and advice. Thanks to J Maynard and D Tracey at
422 SymbioSeas for help with data analysis and GIS methods development. Funding was provided by
423 the Florida Department of Environmental Protection Award No. B7B6F3. The manuscript was
424 greatly improved by comments from C. Woodley, E. Davenport and J. Guyon. The views,
425 statements, findings, conclusions, and recommendations expressed herein are those of the authors
426 and do not necessarily reflect the views of the State of Florida or any of its sub-agencies.

729

730 Table 1. Predictor variables with their description and units used to model potential human and

731 environmental drivers of dark spot disease (DSD) across the Florida Reef Tract.

Predictor variable	Description and units	Min	Max	Data source
Depth	Depth (m) of coral at time of survey	1.1	21.6	Recorded in situ
Host abundance	Total number of host colonies along transect	1	193	Recorded in situ
Year	Survey year	2005	2019	
Habitat characterization	Reef Zone - Thirteen mutually exclusive zones identified from shore to shelf edge corresponding to typical insular shelf and coral reef geomorphology. Examples include Reef Flat, Lagoon, Back Reef, Reef Crest, Fore Reef, Bank/Shelf, Bank/Shelf Escarpment. (Zitello et al 2009)	NA	NA	
	URM GeoForm - Distinct and non-overlapping broad geomorphological structure types that can be mapped by visual interpretation of remotely sensed imagery. Examples include Coral Reef and Hardbottom, Unconsolidated Sediment, Other Delineations, and Unknown. (Zitello et al 2009)	NA	NA	
	URM GeoFormDet - Distinct and non-overlapping more descriptive geomorphological structure types that can be mapped by visual interpretation of remotely sensed imagery. Examples include Rock Outcrop, Boulder, Spur and Groove, Individual Patch Reef, Aggregated Patch Reefs, Aggregate Reef, Reef Rubble, Pavement, Pavement with Sand Channels, Rhodoliths, Sand, Mud, Sand with Scattered Coral and Rock, Artificial, Land, and Unknown. (Zitello et al 2009)	NA	NA	https://myfwc.com/research/gis/regional-projects/unified-reef-map/
	URM Class Lv - (Lv 0-4) The most detailed classification that incorporates GeoFrom and dominant live biotic cover estimates. Examples include Aggregate Reef-Algae (Continuous), Aggregate Reef-Algae (Discontinuous), Aggregate Reef-Algae (Patchy), Aggregate Reef, Live Coral (Discontinuous), Aggregate Reef-Live Coral (Patchy), Aggregate Reef - Live Coral (Sparse), Aggregate Reef-Uncolonized	NA	NA	
The Nature Conservancy Ocean Wealth Data	Mean number of coastal tourist visits that year (within 1, 2, 3, 5, 8, 13, 21 km radius)	0	6,305	https://oceanwealth.org
	Mean spend ($) by coastal tourists that year (within 1, 2, 3, 5, 8, 13, 21 km radius)	0	2,202	
Wastewater: proxy of human presence/influence (impacts to coastal areas)	Number of wastewater treatment facilities (within 13 and 21 km radius)	1	57	
	Mean design capacity (millions gallons/day) of wastewater treatment facilities (within 13 and 21 km radius)	0	113	https://geodata.dep.state.fl.us/
	Amount of wastewater (millions gallons/day) permitted to be processed (within 13 and 21 km radius)	0	113	
Septic/Sewer Areas: proxy for potential sewage pollution	Septic area (area in km^2 known/likely to drain to septic within 1, 2, 3, 5, 8, 13, 21 km radius)	0	230	
	Septic count (total number of known/likely septic 'areas' that intersect 1, 2, 3, 5, 8, 13, 21 km radius)	0	97416	https://www.floridahealth.gov/environmental-health/onsite-sewage/research/fwrmi/index
	Sewer area (area in km^2 known/likely to drain to sewer within 1, 2, 3, 5, 8, 13, 21 km radius)	0	7,437	https://ww10.doh.state.fl.us/pub/bos/inventory/FloridaWaterManagementInventory
	Sewer count (total number of known/likely sewer 'areas' that intersect 1, 2, 3, 5, 8, 13, 21 km radius)	0	403,628	
Land Use: degree of urbanization (affects coastal runoff & pollution)	High intensity land use area (in km2) = Constructed materials account for 80 – 100 % of the total cover. Vegetation, if present, occupies less than 20 % of the landscape.	0	289	https://coast.noaa.gov/digitalcoast/data/ceapregional.html
Water Quality: direct measurements at water surface and reef floor	Mean total phosphorus (um/L) (within 8, 13, 21 km radius)	0.033	0.531	
	Mean silica (um/L) (within 8, 13, 21 km radius)	0.005	7.16	http://serc.fiu.edu/wqmnetwork/
	Total organic carbon (um/L)	18.55	135.24	
	TN-ANTEK 9000–tot nitrogen (um/L)	0.060	13.24	
	Chlorophyll-a (ug/L)	0.169	68.87	
Human population (impacts to coastal areas)	Human population count (total number within 1, 2, 3, 5, 8, 13, 21 km radius)	0	1,564,696	https://www.census.gov/geographies/mapping-files/2010/geo/tiger-data.html
	Housing units (total number within 1, 2, 3, 5, 8, 13, 21 km radius)	0	709,263	

732

733 Table 2. Relative influence (%) of the 18 significant variables that together explained 64.4% of the
734 variation in the number of DSD cases (cross-validated percentage deviance explained = 47.1%).
735 See Table 1 for a more detailed description of the predictor variables.
736

Predictor	Influence (%)
mean silica (um/L) in surface waters within 13 km	18.4
total number of *S. siderea*	16.9
septic area (km^2) within 8 km	10.2
habitat characterization (URM class Lv4)	9.4
depth	8.6
year	7.1
reef zone	5.2
total organic carbon (um/L) in surface waters within 13 km	4
Chlorophyll-a (um/L) in surface waters within 21 km	3.9
total organic carbon (um/L) in surface waters within 8 km	3.8
mean total phosphorous (um/L) in bottom waters within 21 km	2.7
mean spending within 1 km	2.4
septic areas (km^2) within 21 km	1.5
total organic carbon (um/L) in bottom waters within 21 km	1.3
degree of urbanization (m^2) within 8 km	1.3
mean spending within 5 km	1.2
number of septic systems within 8 km	1.1
mean total phosphorous (um/L) in surface waters within 8 km	1.1

746

747 Figure 1. Example of dark spot disease (DSD) in *Siderastrea siderea*. Dark reddish-brown areas
748 indicate disease.

749

750 Figure 2. Benthic survey locations (black dots) from 2005 to 2019 within ecoregions across
751 Florida's Reef Tract. The table summarizes the number of sites surveyed per year.

752

753 Figure 3. Overall DSD prevalence (all sites combined for each year) through time on reefs
754 across the Florida Reef Tract. Dotted lines indicate mean prevalence for the two time periods
755 2005-2012 and 2013-2019.

756

757 Figure 4. Overall frequency of occurrence of DSD (all sites combined for each year) through
758 time. Dotted lines indicate the mean FOC for the two time periods 2005-2012 and 2013-2019.

759

760 Figure 5. Predicted relationship from the BRT model between *Siderastrea siderea* abundance and
761 (A) surface silica concentration within a 13 km radius and (B) septic area within 8 km radius, on
762 the number of DSD cases (fitted values). See Table 1 for a more detailed description of the
763 predictor variables.

764

765

Figure 6. Cumulative DSD prevalence within different ecoregions of the Florida Reef Tract. Number above each bar indicates total number of surveys conducted in each region between 2005 and 2019 (excluding 2017).

Figure 7. Map of the Florida Reef Tract showing the association between DSD prevalence in *S. siderea* and the top three predictor variables among different ecoregions along the Florida Reef Tract. Colored dots indicate sites exceeding the threshold levels for the model's three top predictors of DSD occurrence. Blue dots indicate sites where the threshold levels of *S. siderea* densities are found, yellow dots indicate the threshold for silica concentrations and red dots indicate the threshold for septic areas within 8 km.
